## LIST OF SYMBOLS

SE - The sand equivalent value.
LD - The loss by Decantation given as a percentage.
P - The decimal fraction of the minus no. 200 mesh material in a sample of sand.
A - The sand reading in inches in the sand equivalent test.
K - The ratio of the clay reading minus the sand reading and the sand reading in the sand equivalent test.
$\mathrm{C}-\frac{\mathrm{K}}{\mathrm{P}}$.
LL -The liquid limit of the minus no. 200 mesh fraction.
$\mathrm{K}_{1}$ - Adherence Factor, the ratio in percent between the fraction decanted in the loss by decantation test and the fraction of minus no. 200 mesh material actually present in an aggregate.
$\mathrm{f}^{2}$-Fundamental flexural frequency of vibration squared.

## Introduction

Specifications for concrete aggregates represent a compromise between the desire for a perfect material and the necessity for using materials that are economically available. In many instances the engineer is faced with the problem of writing a specification to limit a certain property and finds that sufficient information concerning that property, or how to measure it is not available. These encounters have resulted in the use of such phrases as "harmful amounts," "excessive amounts" or in the assignment of some arbitrary quantitative measure. As experience is gained these arbitrary quantitative measures have been adjusted first in one direction then in another, resulting in serious loss of confidence in some specifications. One of the examples of this type of specification is in the area of cleanliness of concrete aggregates.

This research project was undertaken to strengthen the knowledge in this area. The specific objectives were:

1. To study methods of test for determining the clay content of concrete aggregates.
2. To determine the effects of clay content on the strength, shrinkage, and durability of concrete.
3. To relate these effects of clay on the properties of concrete to results of tests for determining clay content of the aggregates.

This research included a study of the existing test methods (sand equivalent and loss by decantation) used to detect clay in concrete aggregates, and a study of the effect of various amounts of clay with various liquid limits on the strength, shrinkage, and freeze-thaw durability of concrete. The work necessarily included the determination of clay fraction properties of concrete aggregates from pits within the state of Texas. The concrete testing program included one basic mix design with two coarse aggregates; a siliceous river gravel (all except $B$ series mixes) and a crushed limestone ( $B$ series mixes). A siliceous river sand and one brand of Type I cement were used throughout the program.

Work on this project was conducted over a threeyear period. The exact mix quantities and properties for each mix are given in Tables 7 through 12 in the appendix and the legends on curves indicate the mix series from which the data were taken.

## Summary and Conclusions

#### Abstract

The conclusions developed from this study are based on a limited number of aggregates and concrete batches. Care should be exercised in extending these conclusions to materials other than those studied.

It has been found that the activity as well as the amount of the minus no. 200 mesh fraction of concrete aggregates affects the properties of concrete. Both activity and amount are reflected in the sand equivalent value but not in the loss by decantation. Clay contaminants in concrete aggregate affect concrete properties primarily through their effect on water demand. Concrete strength and shrinkage correlate to a high degree with sand equivalent value and to a slightly lesser degree with water-cement ratio indicating the possibility that the sand equivalent test indicates properties of the aggregate that are not accounted for solely by the aggregates' water demand in concrete.

The basic reactions and mechanisms by which the clay components produced these observed effects are quite complex. Clay particles, being colloidial, are known to possess an adsorbed water layer, attracted and held by the negative electric charge on their surfaces. If this layer contains cations, such as calcium or sodium, it is referred to as the adsorption complex. The nature of this adsorption complex greatly influences the properties of the clay. The ability of a clay particle to attract water and cations and to increase in volume will act to influence the properties of the concrete. As the clay comes in contact with the batch water, water molecules are drawn into the layered clay particle causing an expansion and weakening the particle. The primary influence is apparently due to the increased water demand caused by the presence of these clay fines.

The freeze-thaw durability of the concretes studied is related to the sand equivalent value. Decreases in sand equivalent value bring about decreases in the freezethaw durability of the concretes. However, the mode of deterioration was different in the air entrained and nonair entrained concretes. The non-air entrained concretes exhibited structural failure as indicated by sonic modulus of elasticity determinations but in the air entrained concrete, attrition of the surface reflected by loss in weight was the primary indicator of deterioration.

The need for sufficient processing to produce a relatively clean aggregate can best be emphasized by considering the quantitative effects on the properties of the concrete. The data developed indicate that for a given fine aggregate, as the sand equivalent value changes from 60 to 80 , the concrete properties will exhibit the following changes.

1. Gain in 7-day compressive strength of $15 \%$.
2. Gain in 28 -day compressive strength of $16 \%$.
3. Gain in 7 -day modulus of rupture of $13 \%$.
4. Gain in 28 -day modulus of rupture of $12 \%$.
5. Increase in durability (according to ASTM C290) of non-air entrained concrete of $60 \%$.
6. Insignificant change in durability of air entrained concrete (air content approximately $5 \%$ ).

7: Decrease in relative 28-day shrinkage of $17 \%$.
8. Decrease in relative 120 -day shrinkage of $15 \%$.
9. Decrease in concrete mixing water demand of $9 \%$.

On the basis of concrete strength and shrinkage, the present Texas Highway Department sand equivalent specification minimum of 80 seems quite reasonable. The freeze-thaw durability test results emphasize the need for precise control of air entrainment where fine aggregates with sand equivalent values close to the specification limit are to be used.

The loss by decantation test was found to measure only the amount of minus 200 mesh material in an aggregate. It fails to distinguish between active clay material and durable, inert minerals. The sand equivalent test, on the other hand, indicates both amount and activity (as measured by the liquid limit) of the minus 200 mesh fraction and is a more desirable indicator of the quality of fine aggregate.

## Sand Equivalent and Loss by Decantation Tests

The sand equivalent (Tex-203-F) and loss by decantation (Tex-406-A) test methods used in this program are given in the Appendix.

The sand equivalent test was developed by F. N. Hveem while he was serving as Materials and Research Engineer, California Division of Highways. It was to be used as a rapid means of quality control of fine aggregate for bases, subbases, bituminous mixtures, and portland cement concrete. The procedure developed by Hveem did not require that the sample be oven dried prior to testing and consequently results could be produced within 40 minutes.

The testing program was carried out in two phases -the first, a study of the relationship between the sand equivalent and loss by decantation tests, and the second, a more detailed investigation of the sand equivalent test. In the first phase, 1.5 samples of concrete sand from various locations in Texas were obtained. Values obtained from tests run on these samples are plotted in Figure 1 and are presented in Table 2.

In order to investigate the effect of liquid limit on the results of the two tests, artificially contaminated ag-

Figure 1. Relationship between loss by decantation and sand equivalent value for natural aggregate samples.
gregates were blended and tested. The sand used was a high quality concrete sand which was washed in the laboratory with a detergent to remove all minus 200 mesh material. The contaminants used were: (1) pure silica flour with a liquid limit of zero, (2) a natural clay with a liquid limit of 35 percent, (3) a silica-montmorillonite mixture with a liquid limit of 200 percent, (4) a silicamontmorillonite mixture with a liquid limit of 400 percent, and (5) pure montmorillonite with a liquid limit of 640 percent. Results of tests performed on these sands are given in Table 2.

Figures 2 and 3 demonstrate the effect of liquid limit for two different percentages of contaminant on the results of the two tests. The sand equivalent values of Figure 3 are in close agreement with those reported by Clough and Martinez (4.)*. It can be seen that the variation in liquid limit of the contaminant has little or no effect on loss by decantation results, but has a very pronounced effect on the sand equivalent value.

The relationship betweeñ loss by decantation and sand equivalent test values can be derived in the following manner. If the symbols of Figure 4 are used in the definition of the sand equivalent value, it can be written:

$$
\begin{array}{ll}
\text { or } \quad \mathrm{SE}=100 \mathrm{~A} /(\mathrm{A}+\mathrm{KA}) \\
\mathrm{SE}=100 /(1+\mathrm{K}) \tag{1b}
\end{array}
$$

For a given material the factor K can be written as another factor $C$ times $P$, where $P$ is the decimal fraction of the contaminant in the sample. Equation (lb) then becomes:

$$
\begin{equation*}
\mathrm{SE}=100 /(\mathrm{l}+\mathrm{CP}) \tag{2}
\end{equation*}
$$

This equation can be written

$$
\begin{equation*}
\mathrm{C}=(100-\mathrm{SE}) /(\mathrm{SE})(\mathrm{P}) \tag{3}
\end{equation*}
$$

If values of $C$ are plotted against values of the liquid limit (using the data from Table 2) and the data points fitted with a curve by the least squares method using $\mathrm{C}=\mathrm{A}_{1}(\mathrm{LL})+\mathrm{A}_{2}$ as a model. The resulting equation is

$$
\begin{equation*}
\mathrm{C}=0.1318(\mathrm{LL})+1.79 \tag{4}
\end{equation*}
$$

Figure 2 shows the average value of the loss by decantation was 2.3 percent for 2.5 percent minus 200 mesh material. If these values are used in the equation,

$$
\begin{equation*}
\mathrm{LD}=\mathrm{K}_{1} \mathrm{P} \tag{5}
\end{equation*}
$$

the value of $K_{1}$ is found to be 92.
Equation (5) can now be written,

$$
\begin{equation*}
\mathrm{P}=\mathrm{LD} / 92.0 \xlongequal{=} 0.01087 \mathrm{LD} \tag{6}
\end{equation*}
$$

The relationship between sand equivalent (SE) and loss by decantation (LD) can be found by substituting.

[^0]

Figure 2. Relationship between loss by decantation and liquid limit of contaminant.
the expression for C from Equation (4) and the expression for $P$ from Equation (5) into Equation (2). The resulting equation is

$$
\mathrm{SE}=\frac{100}{1+\frac{\mathrm{LD}}{\mathrm{~K}_{1}}(0.1318 \mathrm{LL}+1.79)}
$$

A comparison of calculated and measured values of sand equivalent for both the natural samples and manufactured samples is illustrated in Figure 5. The values for samples 106 through 110 compare very closely, but for samples 1 through 10 the calculated value is somewhat higher than the measured value.

There are several possible reasons for the smaller degree of correlation between calculated and measured sand equivalent values in the naturally occurring samples. First, the mode of occurrence of the clay, whether finely divided or as a coating, should influence the decantation loss creating a variable value of $K_{1}$. Second, properties of the sand, other than the minus no. 200 mesh fraction probably influence the sand equivalent value. Other researchers $(3,8)$ have shown that other properties of a sand are reflected in the sand equivalent value. Tests performed by Chamberlin (3) indicate that in a few sands a "generation of fines" takes place during the shaking operation of the sand equivalent test. It is very unlikely that this "generation of fines" takes place
in the loss by decantation test due to the lack of any vigorous scrubbing action.

There are several opinions as to the meaning of the sand equivalent value, i.e., which of the various properties of sands are reflected in the sand equivalent value. Nevertheless, the fact remains that the test correlates quite well with the strength, shrinkage, and durability of the concretes tested in this program, and research conducted by the California Division of Highways (8) has resulted in a correlation between mortar shrinkage and sand equivalent value of natural sands.

Initial investigations showed that the quality of concrete was affected by both amount and type of clay in the aggregates. It was felt that the quality of the concrete is also affected by the relative amount of the total clay content that occurs as a coating on the aggregate particles. In order to investigate such an effect, a means of detecting the relative amount of clay coating was desired. An attempt was made to modify the sand equivalent test procedure to detect relative amounts of clay coating. Two techniques were employed. First, a given sample was divided by quartering to yield four test specimens. A sand equivalent test was then run on each of these specimens-one specimen at zero shakes, another at 30 , another at 60 , and finally one at 90 shakes. The second technique used was to obtain a representative sample and run a sand equivalent test at zero shakes,

Figure 3. Relationship between sand equivalent and liquid limit of contaminant.
then siphon off the liquid down to the specified height for shaking and subject the specimen to 30 shakes. A second set of readings was taken. These siphoning and shaking operations were repeated at 30 shake intervals

CLAY READING

SAND READING

Figure 4. Illustration of clay and sand reading in sand equivalent test.
with readings taken after each shaking until a total of 90 shakes were imparted to the specimen. A number of tests were run up to 180 shakes.

From these test results, a plot of sand equivalent against total number of shakes was made. It was thought that the shape of the curve relating sand equivalent value with number of shakes could be used as a measure of the relative amount of clay occurring as a coating.

Some 200 tests were run on 2 l samples from various locations in Texas. Laboratory prepared samples were also tested in this phase. It was found that various preparations of laboratory samples using sand from a single source produced curves with various degrees of curvature. Quantitative measures of this curvature would indicate the relative ease with which a clay can be separated from the aggregate. Curves of the type desired are shown in Figure 6. Curves developed from commercially produced aggregates however, have a general downward trend and the curvatures artificially produced were not observed. Figure 7 illustrates two curves typical of those developed. No practical significance was discovered for the data developed in this area of the program except that the "generation of fines" phenomenon described by Chamberlin (3) seemed indicated by tests on some of the samples.

As stated earlier, this work included the determination of clay fraction properties of commercially produced

concrete aggregates. The clays were identified by x-ray diffraction, cation-exchange capacity, and exchangeable cation determinations which were performed by Dr. G. W. Kunze of the Texas A\&M University Soil Physics

Department. Figure 8 is a typical x-ray diffraction pattern obtained from one of the tests. Other related properties of the clays are given in Table 1. In general most of the clays are predominantly montmorillonite.

## Strength of Concrete

Initial testing conducted during the first year was aimed at determining the qualitative effects of contaminant liquid limit on the properties of concrete. Therefore a very wide range of liquid limit ( 0 to 640 percent) was employed. Contaminant percentages varied from 0 to 1.6 percent of the total aggregate by weight.

The effects of liquid limit of contaminant on the flexural and compressive strength is illustrated in Figures 9 through 12. In each case a significant reduction in strength is caused by increasing the liquid limit of the contaminant. The mixes included contaminants with very high liquid limits which were used to determine the relative importance of this factor.

The fact that concrete strength is influenced by both the amount and liquid limit of the contaminant indicated the need for more precisely defining these effects within the practical range found in concrete aggregates. Additional mixes. ( C and E series) were designed to accomplish this.

The data relating strength and shrinkage to sand equivalent value and water-cement ratio have been ap-

Figure 9. Influence of liquid limit of contaminant (nominally $1.6 \%$ clay) on 7 -day modulus of rupture.

Figure 10. Influence of liquid limit of contaminant (nominally. $1.6 \%$ clay) on 28-day modulus of rupture.
proximated by straight lines fitted by the least squares method (5). The control batch from each series of batches was used as the basis for calculating the relative strength and shrinkage for each particular series. The equation for each of the lines and the respective correlation coefficient are given on each figure. Dashed lines representing plus and minus 10 percent of the ordinate have been drawn on each figure to more clearly illustrate the degree of data scatter.

Figures 13 and 14 , illustrate the effect of amount of clay contaminant at the $35 \%$ liquid limit level on the 7 and 28 -day concrete compressive strength. The correlation coefficients for both lines ( 0.85 for 7 -day and 0.89 for 28 -day) are high, indicating a good correlation in each case. The plus and minus 10 percent lines include all but 5 out of 37 data points in each of the figures.

The relationship between modulus of rupture at 7 and 28 days and sand equivalent value is illustrated in Figures 15 and 16. The 7-day test data yield a lower correlation coefficient (0.74) than that found in the

Figure 20. Relationship between 7-day compressive strength and water-cement ratio.

Figure 21. Relationship between 28-day compressive strength and water-cement ratio.

28-day test (0.84). Nevertheless both correlation coefficients are relatively high. A sand equivalent value of 80 indicates a reduction in modulus of rupture of about 10 percent when compared to mixes containing sands with a sand equivalent value of 100 .

As in the case of modulus of rupture, the compressive strength correlates quite well with sand equivalent value as shown in Figures 17 and 18. Decreases in sand equivalent values cause a decrease in compressive strength. A decrease in compressive strength of about 11 percent can be expected if the sand equivalent value is changed from 100 to 80.

The water requirement for a given slump has been found to correlate quite well with sand equivalent value (correlation coefficient 0.83). This relationship is illustrated in Figure 19. The correlation of water-cement ratio with compressive strength is illustrated in Figures 20 and 21. Here and in Figures 24 and 25, batches with
water-cement ratios of 0.6 were used as the control batches. The correlation coefficients for these two curves are slightly lower than those for the strength-sand equivalent correlations.

The fact that the correlation coefficient of the strength vs. sand equivalent value is only slightly higher than the strength vs. water-cement ratio indicates that almost all the variation in strength can be attributed to the increased water demand of the sands having lower sand equivalent values.

Test data obtained during the first two years did not make this relationship evident, but the accumulation of data during the last year has properly illustrated this relationship. The statement that fine aggregate affects the properties of concrete primarily through its effect on water requirement $(3,8)$ is supported by the data obtained from this study.

## Shrinkage of Concrete

Shrinkage of the concretes studied correlates to some degree with water-cement ratio but to a higher degree with sand equivalent value as illustrated by Figures 22 through 25. In each case a decrease in sand equivalent value or an increase in water-cement ratio causes an increase in shrinkage.

Hveem and Tremper (8) reported a correlation coefficient of 0.66 between drying shrinkage of mortar and sand equivalent value of commercially produced con: crete sands. However, when the absorption of the sand was included the correlation was significantly improved (correlation coefficient 0.83 ). Chamberlin (3) reports
". . . Interestingly, sand equivalents of the experimental aggregates also correlate with drying shrinkage and to a rather high degree . . .
"The relative contribution of aggregate elasticity and clay content (as measured by sand equivalent) to the observed shrinkage cannot be distinguished by statistical methods alone. This is because the two factors correlate significantly with one another (coefficient of 0.80 ), that is, sands with low elastic moduli tend also to have low sand equivalents and both, therefore, would be expected to influence shrinkage in the same direction and in unison . . ."

## Durability of Non-Air Entrained Concrete

A series of ten concrete batches were mixed for this determination of relative durability. The amount of contaminant ranged from 0 to 5.25 percent of the total aggregate by weight with three levels of liquid limit ( 0 , 35 , and 70 percent) used for each amount of contaminant. Material quantities and properties of the plastic concrete for these mixes are given in Table 11. Two
$3^{\prime \prime}$ by $3^{\prime \prime}$ by $16^{\prime \prime}$ prismatic specimens were cast from each mix and moist cured at $72 \pm 2^{\circ} \mathrm{F}$ for 14 days prior to testing. These specimens were then subjected to freezethaw durability testing in accordance with ASTM C290.

These concretes proved to be quite susceptible to freeze-thaw deterioration. Deterioration of the concretes manifested itself in surface scaling and loss of structural

Figure 26. Photograph of specimens from D series batches after completion of freeze-thaw testing by ASTM C290.

Figure 27. Relationship between freeze-thaw durability of non-air entrained concrete and sand equivalent value.

Figure 28. Relationship between no. of freeze-thaw cycles for fundamental flexural frequency squared to reach 20 percent of its original value and sand equivalent value.
integrity as indicated by sonic modulus of elasticity determinations. Figure 26 shows the specimens after testing was terminated at 300 cycles.

Figure 27 shows the batch durability factors plotted as a function of sand equivalent value. The durability factor was calculated as outlined in ASTM C290 using 300 cycles and $60 \%$ relative dynamic modulus of elasticity. With the exception of two errant points a very definite trend is produced-a decrease in sand equivalent value is accompanied by a very significant decrease
in durability factor. The two excessively high points are not believed to be representative and were not considered in establishing the data trend. This opinion is supported somewhat by Figure 28 where the relative fundamental flexural frequency of vibration squared has been carried to 20 percent. The two high data points are now more in line with the previously assumed data trend. It can be seen that aggregates meeting sand equivalent specification limits of 80 can result in a $50 \%$ loss in durability in non-air entrained concrete.

## Durability of Air Entrained Concretes

Specimens from batches A13 and A15 through A19 were subjected to 400 cycles of slow freezing and thawing in a chest type freezer. Results of these tests were inconclusive and only very slight surface deterioration was observed. The specimens were stored until a later date when they were subjected to freeze-thaw testing according to ASTM C290. Deterioration of most of these specimens was not indicated by fundamental frequency determinations but did show itself in changes in weight due to surface deterioration. The exceptions were the specimens containing 640 liquid limit contami-
nant (batch A19). These specimens completely disintegrated after 40 cycles and were removed from testing. Figure 29 presents the weight loss after 300 cycles (except for batch A19) of ASTM C290 testing, and Figure 30 shows these specimens after completion of testing.

The tests indicate an insignificant loss in durability of specimens containing fine aggregates with contaminant liquid limits of $35 \%$ or less (sand equivalent yalues of 80 or above) when the proper amount of air is entrained in the concrete.

## TEXAS HIGHWAY DEPARTMENT

 MATERIALS AND TESTS DIVISION
## Sand Equivalent Test

## Scope

This test method, which is a modification of California Test Method No. 217-C, provides a means for determining the relative proportion of detrimental fine dust or clay-like particles in soils or fine aggregates (that portion of the aggregate passing the No. 4 sieve).

## Apparatus

1. A transparent plastic graduate cylinder $11 / 4$-inch inside diameter, about 17 inches in height, and graduated up to 15 inches in intervals of one-tenth inch starting at the base. A rubber stopper to fit the mouth of the graduated cylinder, Figure 1.
2. An agitator tube-a brass, stainless steel, or copper tube of $1 / 4$-inch outside diameter approximately 20 inches in length with one end closed to form a wedgeshaped point. Two holes (drill size 60) are drilled laterally through the flat side of the wedge near the point.
3. A weighted foot assembly, for measuring the height of sand in the cylinder, consists of a metal rod connected to a foot, with flat, smooth surface, at lower end and an attached weight at upper end sufficient in size to give the assembly a total weight of 1000 grams. The foot has a conical upper surface and three small screws to center it loosely in the cylinder. A cap to fit the top of cylinder is bored to fit loosely around the rod and serves to center the weighted foot assembly in the cylinder. See Figure 1A for detail dimensions of parts.
4. A 1 -gallon glass bottle equipped with siphon assembly consisting of a 2 -hole rubber stopper and pieces of glass or copper tubing.
5. A 4 -foot length of plastic or rubber tubing with pinch clamp to control flow of liquid. The flexible tub. ing connects the open end of agitator tube with siphon assembly of bottle placed on a shelf three feet above the work surface. The tubing should fit snugly on siphon and agitator tube and be of convenient working length.
6. A No. 4 sieve with square openings
7. A 3 -ounce measuring can
8. A wide-mouth funnel for transferring material into plastic cylinder
9. A watch or clock reading in minutes and seconds.
10. Graduate--a 100 cc . glass cylinder graduated in increments of 2 cc . or less.

Note: The equipment listed above with the exception of the graduate is shown in Figure 1 .

## Materials

1. Stock solution. Prepare the stock solution with the following:

454 grams (1 pound) tech. anhydrous calcium chloride, or 601 grams dihydrate, or 896 grams of hexahydrate calcium chloride

Figure 1.
2050 grams ( 1640 ce.) U.S.P. glycerine 47 grams ( 45 cc .) formaldehyde ( 40 percent by volume)
Dissolve the 454 grams calcium chloride in $1 / 2$-gallon of distilled or demineralized water. Cool the solution and filter it through a Whatman No. 12, or equivalent, filter paper. Add the 2050 grams of glycerine and 47 grams of formaldehyde to the filtered solution, mix well and dilute to one gallon with distilled or demineralized water.
2. Working calcium chloride solution. Prepare the working solution by diluting 88 cc . of the stock calcium chloride solution to one gallon of distilled or demineralized water. A good quality tap water may be used if the purity is such that it does not affect the test results.

## Test Record Forms

Record test data on work sheet, Form No. D-9-F7.

## Preparation of Sample

1. Select a representative sample of material and dry to constant weight at a temperature of $200^{\circ}$ to $230^{\circ} \mathrm{F}$.
2. Use the No. 4 sieve with square openings and separate the sample into two portions, breaking up lumps which consist of particles obviously finer than the No. 4 sieve.
3. Secure the sand equivalent test sample from the portion passing the No. 4 sieve by carefully reducing the amount of material to laboratory test size. Split or quarter the material to obtain enough to fill the 3 -ounce measuring can (approximately 110 grams). To insure representative samples when working with a material that is

WEIGHT FOOT ASSEMBLY

| Adj. Screws-R.Hd. | $\frac{1^{\prime \prime}}{4} \times 3-48$ | Brass |
| :--- | :--- | :--- |
| Foot | $1^{\prime \prime}$ Dia. $\times .75^{\prime \prime}$ | Bronze |
| Guide | $1.50^{\prime \prime}$ Dia. $\times \frac{1^{\prime \prime}}{4}$ | Brass |
| Weight* | $2^{\prime \prime}$ Dio. $\times 2.078$ | C.R.StI. |
| Rod | Dio. $\times 17.5^{\prime \prime}$ | Brass |
| Weight Foot Assy. minus Guide $=1 \mathrm{Kg}. \pm 5 \mathrm{~g}$ |  |  |

predominantly coarse (No. 4 to No. 10 material), the sample should be separated into No. 4 to No. 10 and minus No. 10 sizes, then recombined in proper proportions to produce a uniform sample.

## Procedure

1. Shake the bottle of working calcium chloride solution well and siphon about 4 inches of the solution into the plastic cylinder. Check the agitator tube to be certain that the solution flows freely.
2. Use the small funnel and transfer the sample from the measuring can into the plastic cylinder, Figure 2. Stopper the cylinder. Tap the bottom of the cylinder on the heel of the hand several times to remove air bubbles and promote the thorough wetting of the sample. Remove stopper. Using a minimum amount of solution wash the particles clinging to wall of cylinder down into the mixture.
3. Allow the cylinder with contents to stand undisturbed, free of any vibration, for ten minutes plus or minus one minute.

Figure 2.

Figure 3.

Figure 4.
4. At the end of the soaking period place the stopper in end of cylinder, partially invert the cylinder and simultaneously shake it to dislodge the material from the bottom. After loosening the material, hold the cylinder in a horizontal position and shake it vigorously by alternately throwing the contents of the cylinder from end to end ( $9^{\prime \prime}$ plus or minus $l^{\prime \prime}$ throw) as illustrated in Figure 3. Make 90 cycles in approximately 30 sec onds; a cycle consists of a complete back and forth motion.
5. Following the mixing operation, place the cylinder on the work table, remove stopper and wash down the cylinder wall with the agitator tube. Then force the agitator through the material to the bottom of the cylinder by gently twisting and shoving while the solution flows from the tip of the tube. Continue smoothly jabbing the agitator tube up and down with a gentle twisting motion while slowly rotating the cylinder in a vertical position to flush the fine clay-like material up into suspension above the coarse sand particles.
6. Continue the operation until the cylinder is filled to the 15 -inch mark. Then slowly remove the agitator tube without shutting off the flow so that the level of the liquid is maintained at about 15 inches. Regulate the flow of the solution and adjust the level of solution to 15 inches when the agitator tube is entirely withdrawn.
7. Allow the cylinder and contents to stand undisturbed for a period of 20 minutes plus or minus 15 seconds. Start the timing immediately after the removal of the agitator tube.
8. After the 20 -minute sedimentation period, read and record the level of the top of the clay suspension to the nearest 0.1 inch, Figure 4.
9. Gently lower the weighted foot assembly in the cylinder until it comes to rest on top of the sand. Keep one of the centering screws in contact with the cylinder wall near the graduation marks so that it can be seen. When the weighted foot has come to rest, read the level
of the centering screw and record as the sand reading to nearest 0.1 inch (Figure 5).

Should either reading in Steps 8 or 9 fall between two divisions on the graduated cylinder, the reading should be raised to the higher reading. (Example: 8.68 $=8.7^{\prime \prime}, 6.21=6.3^{\prime \prime}$ )

## Calculations

Calculate the sand equivalent value to the nearest 0.1 using the following formula:

$$
\mathrm{SE}=\frac{\text { Sand Reading }}{\text { Clay Reading }} \times 100
$$

## Reporting Test Results

Report the sand equivalent test results as a whole number. For example:
$\mathrm{SE}=\frac{3.2}{6.9} \times 100=46.4$, report the value as 47.

# Decantation Test for Concrete Aggregates 

## Scope

This test method describes a procedure for determining the amount of clay and silt in concrete aggregates. The procedure provides a means for measuring the percentage loss in terms of absolute volume which is equal to the percentage loss by weight, assuming that all of the particles have the same specific gravity.

## Part I <br> Laboratory Method for Coarse Aggregate

## Apparatus

1. Balance with 5000 gram capacity sensitive to 0.1 gram
2. Drying oven maintained at $230^{\circ} \mathrm{F}$
3. Graniteware milk pan 12 inches in diameter and 5 inches deep
4. Sieve-a standard U.S. No. 200 sieve
5. Sample splitter or quartering cloth

## Test Record Forms

Record test data on Form D9.A-3 and report results on Form No. 272 or Field Laboratorv Aggregate Sieve Analysis Report Form No. 310.

## Procedure

1. Obtain a representative sample of the coarse aggregate and reduce the material to laboratory test size, a sufficient quantity to yield approximately 3000 grams when dry, by means of the sample splitter or quartering cloth.
2. Dry the aggregate to constant weight at a temperature of $230^{\circ} \mathrm{F}$. and obtain the dry weight of the sample to the nearest 0.1 gram.
3. Place the coarse aggregate into a graniteware pan, cover with tap water and allow to soak for 24 hours.
4. After the aggregate has been thoroughly saturated to allow the clay particles to disintegrate, use the hands to vigorously agitate the material and then decant the wash water over the No. 200 sieve. Add water and repeat washing and decanting until the wash water is clear. Recover any of the aggregate that spilled onto and retained on the No. 200 sieve.
5. Dry the washed material to constant weight in an oven at a temperature not to exceed $230^{\circ} \mathrm{F}$., weigh and record the net weight of the washed aggregate.

## Calculations

Calculate the percentage of clay and silt or loss from the following expression:

Percent loss $=\frac{W_{1}-W_{2}}{W_{1}} \times 100$ (Decantation)
Where:
$W_{1}=$ Original dry weight of aggregate
$W_{2}=$ Dry weight of aggregate after washing

Part II<br>Field Method for Concrete<br>Aggregates<br>Also<br>Laboratory Method for Fine<br>Aggregate

## Apparatus

1. Scale or balance with 5000 grams capacity, sensitive to 1 gram.
2. Wide-mouth funnel
3. Calibrated pycnometer, Figure 1, Test Method Tex-403-A
4. Sieve-Standard U. S. No. 200 sieve. (Required in laboratory, optional in field)
5. A watch or clock with second hand
6. Sample splitter or large pan
7. Towel or lint-free cotton cloth

## Test Record Forms

Record test data on Work Sheet Form D9-A-3 and report test data on Form 272.

## Procedure

1. Thoroughly mix the representative sample and secure a portion weighing approximately 1200 grams. The sample need not be weighed and the moisture content of the material is not considered since these factors have no bearing upon the test values.
2. Place the sample into the half-gallon pycnometer jar and cover with water.
(a) If the material is no drier than saturated, surface-dry, proceed immediately to Step 3 below.
(b) If the moist condition of the material is in doubt, or if the material is drier than saturated, surfacedry, allow to stand undisturbed for at least 24 hours.
3. Then fill the jar with water to within $1 / 2$ inch of the rim, screw the pycnometer cap on the jar until the match marks coincide and then fill completely with water. Stop the hole in the cap with finger and roll the pycnometer to free all entrapped air. Raise and lower the jar in such a manner that the material will flow back and forth in the jar while it is being rolled. Set the pycnometer on work bench and refill the cap to remove any air bubbles. Take precautions to prevent loss of fine material while removing the entrapped air. Use the towel to dry the outside of the pycnometer, fill level full with water and weigh. Record the weight to the nearest 0.1 gram as $Z_{1}$.
4. When testing sand, close the opening in the cap with the finger or thumb and agitate the contents of the pycnometer by rolling the pycnometer with a swinging motion. When testing coarse aggregate, the pycnometer
should be rolled gently in order to avoid breaking the jar. Place the jar in an upright position and allow the very fine particles to settle for 15 seconds. Remove the cap from the jar and slowly pour out the liquid, taking care to lose none of the fine material. Only the material in suspension should be decanted. Repeat the above operation until the water above the fine aggregate is reasonably clear after a 15 second settling period.

Note: As a precaution against loss of material, it is recommended that the water be decanted into a No. 200 sieve.
5. Recover any material which may be retained on the No. 200 and return to the pycnometer. Screw the pycnometer cap on the jar and fill with water. Dry the outside of the pycnometer and complete filling the cap level with water. Weigh and record the weight as $\mathrm{Z}_{2}$.

## Calculations

Calculate the percent loss by decantation as follows:

$$
\text { Percent loss }=\frac{\mathrm{Z}_{1}-\mathrm{Z}_{2}}{\mathrm{Z}_{1}-\mathrm{Y}} \times 100
$$

Where:
$\mathrm{Z}_{1}=$ weight of pycnometer containing sample and water to fill, before washing
$\mathrm{Z}_{2}=$ weight of pycnometer containing sample and water to fill, after washing
$Y=$ weight of the pycnometer filled with water at approximately the same temperature at which $\mathrm{Z}_{1}$ and $\mathrm{Z}_{2}$ were determined.

## Notes

The percentage by weight of material lost by decantation is equal to the percentage by absolute volume,

Figure 1.
assuming that the specific gravity of the material lost to be the same as that of the particles remaining. In actual practice, the difference is negligible.

Figure 2.
