•

PREFACE

This report presents an analytical tool for the solution of plane-frame structures. The computer program developed for the solution is intended to be well suited for solving complex structures with a minimum of hand calculations.

The solution techniques developed rely on the linearly elastic behavior that many plane frames exhibit under design loads. This linearity allows the user to solve a structure for many loading cases and combinations of loading cases at a cost only slightly greater than that of a single solution.

This is the twenty-first in a series of reports that describe work under Research Project No. 3-5-63-56, "Development of Methods for Computer Simulation of Beam-Columns and Grid-Beam and Slab Systems". Reports No. 56-1, 56-3, 56-4, 56-7, and 56-14 provide background information for this report.

Duplicate copies of the program deck and test data cards for the example problems in this report may be obtained from the Center for Highway Research, The University of Texas at Austin.

Thanks are due to the members of the staff of the Center for Highway Research for their assistance in producing this report.

LIST OF REPORTS

Report No. 56-1, "A Finite-Element Method of Solution for Linearly Elastic Beam-Columns" by Hudson Matlock and T. Allan Haliburton, presents a finiteelement solution for beam-columns that is a basic tool in subsequent reports.

Report No. 56-2, "A Computer Program to Analyze Bending of Bent Caps" by Hudson Matlock and Wayne B. Ingram, describes the application of the beamcolumn solution to the particular problem of bent caps.

Report No. 56-3, "A Finite-Element Method of Solution for Structural Frames" by Hudson Matlock and Berry Ray Grubbs, describes a solution for frames with no sway.

Report No. 56-4, "A Computer Program to Analyze Beam-Columns under Movable Loads" by Hudson Matlock and Thomas P. Taylor, describes the application of the beam-column solution to problems with any configuration of movable nondynamic loads.

Report No. 56-5, "A Finite-Element Method for Bending Analysis of Layered Structural Systems" by Wayne B. Ingram and Hudson Matlock, describes an alternating-direction iteration method for solving two-dimensional systems of layered grids-over-beams and plates-over-beams.

Report No. 56-6, "Discontinuous Orthotropic Plates and Pavement Slabs" by W. Ronald Hudson and Hudson Matlock, describes an alternating-direction iteration method for solving complex two-dimensional plate and slab problems with emphasis on pavement slabs.

Report No. 56-7, "A Finite-Element Analysis of Structural Frames" by T. Allan Haliburton and Hudson Matlock, describes a method of analysis for rectangular plane frames with three degrees of freedom at each joint.

Report No. 56-8, "A Finite-Element Method for Transverse Vibrations of Beams and Plates" by Harold Salani and Hudson Matlock, describes an implicit procedure for determining the transient and steady-state vibrations of beams and plates, including pavement slabs.

Report No. 56-9, "A Direct Computer Solution for Plates and Pavement Slabs" by C. Fred Stelzer, Jr., and W. Ronald Hudson, describes a direct method for solving complex two-dimensional plate and slab problems.

Report No. 56-10, "A Finite-Element Method of Analysis for Composite Beams" by Thomas P. Taylor and Hudson Matlock, describes a method of analysis for composite beams with any degree of horizontal shear interaction. Report No. 56-11, "A Discrete-Element Solution of Plates and Pavement Slabs Using a Variable-Increment-Length Model" by Charles M. Pearre, III, and W. Ronald Hudson, presents a method of solving for the deflected shape of freely discontinuous plates and pavement slabs subjected to a variety of loads.

Report No. 56-12, "A Discrete-Element Method of Analysis for Combined Bending and Shear Deformations of a Beam" by David F. Tankersley and William P. Dawkins, presents a method of analysis for the combined effects of bending and shear deformations.

Report No. 56-13, "A Discrete-Element Method of Multiple-Loading Analysis for Two-Way Bridge Floor Slabs" by John J. Panak and Hudson Matlock, includes a procedure for analysis of two-way bridge floor slabs continuous over many supports.

Report No. 56-14, "A Direct Computer Solution for Plane Frames" by William P. Dawkins and John R. Ruser, Jr., presents a direct method of solution for the computer analysis of plane frame structures.

Report No. 56-15, "Experimental Verification of Discrete-Element Solutions for Plates and Slabs" by Sohan L. Agarwal and W. Ronald Hudson, presents a comparison of discrete-element solutions with the small-dimension test results for plates and slabs, along with some cyclic data on the slab.

Report No. 56-16, "Experimental Evaluation of Subgrade Modulus and Its Application in Model Slab Studies" by Qaiser S. Siddiqi and W. Ronald Hudson, describes an experimental program developed in the laboratory for the evaluation of the coefficient of subgrade reaction for use in the solution of small dimension slabs on layered foundations based on the discrete-element method.

Report No. 56-17, 'Dynamic Analysis of Discrete-Element Plates on Nonlinear Foundations" by Allen E. Kelly and Hudson Matlock, presents a numerical method for the dynamic analysis of plates on nonlinear foundations.

Report No. 56-18, "Discrete-Element Analysis for Anisotropic Skew Plates and Grids" by Mahendrakumar R. Vora and Hudson Matlock, describes a tridirectional model and a computer program for the analysis of anisotropic skew plates or slabs with grid-beams.

Report No. 56-19, "An Algebraic Equation Solution Process Formulated in Anticipation of Banded Linear Equations" by Frank L. Endres and Hudson Matlock, describes a system of equation-solving routines that may be applied to a wide variety of problems by utilizing them within appropriate programs.

Report No. 56-20, "Finite-Element Method of Analysis for Plane Curved Girders" by William P. Dawkins, presents a method of analysis that may be applied to plane-curved highway bridge girders and other structural members composed of straight and curved sections.

Report No. 56-21, "Linearly Elastic Analysis of Plane Frames Subjected to Complex Loading Conditions" by Clifford O. Hays and Hudson Matlock, presents a design-oriented computer solution of plane frame structures that has the capability to economically analyze skewed frames and trusses with variable eross-section members randomly loaded and supported for a large number of loading conditions.

vi

ABSTRACT

A linearly elastic solution for the computer-aided analysis of plane frames is presented. The computer program which is developed features input formats which greatly reduce the manual preparation of data.

The solution uses a variation of the basic discrete-element beam-column model for the evaluation of member stiffness and fixed-end-force properties. The new discrete-element model allows flexural and axial rigidity as well as lateral, axial, and rotational values of loading and elastic restraint to vary randomly along the length of the member. Input is not restricted to values lumped at certain discrete stations but may be input in normal engineering values at any point on the member. In addition, options provided do not require the transferring of loads and dimensions from one axis to another by the user.

Frame displacements are obtained by standard matrix techniques modified to utilize the time and storage reductions possible for linearly elastic plane frames. The frame geometry may vary randomly and still be input in a simple and straightforward manner.

Options are provided to permit the analysis of a structure for several loading cases and combinations of cases with a minimum of new input and computer time.

KEY WORDS: structural engineering, frame analysis, plane frames, computer program, discrete element, soil-structure interaction, matrix analysis.

SUMMARY

A computer program for the direct linearly elastic analysis of complex bridge bents and other highway structures has been developed and is reported herein. Rigid frames, trusses, continuous beams, and other planar structures may be analyzed using the program.

The beam-column model previously reported has been modified so that loads and restraints may act both normal and parallel to the members of the frame. This allows the designer to consider vertical or inclined piles as an integral part of the frame, even if the pile is supported by lateral and axial soil restraints.

The description of loads, cross-sectional properties, and soil supports is completely general as in previous beam-column models. In addition, the loads and changes in cross-sectional properties and soil supports may be specified at any point along the member.

The geometry of the frame and the directions of the loads may be input in a manner both natural and convenient to the designer.

Options are provided that permit the designer to analyze structures for the multitude of loading cases required by the AASHO code. These options allow the designer to consider a large number of loading conditions economically. This page replaces an intentionally blank page in the original. -- CTR Library Digitization Team

IMPLEMENTATION STATEMENT

An extremely useful tool for the analysis of highway bridge structures has been developed in this study. The computer program described in the report is capable of handling large, skewed, randomly loaded plane-frame structures, and smaller and more regular structures may be input quickly for an economical solution. Rigid frames, beams, and trusses are analyzed by the same program.

In developing the program, emphasis was placed on maintaining complete generality of input. A skewed bridge bent with piles on lateral and axial soil supports can be easily input. At the same time, it was recognized that many frames are more regular and have simpler support conditions. These simpler problems can also be solved efficiently by the designer using the program.

One outstanding design-oriented feature of the program is its ability to superimpose the effects of a large number of loading conditions. A designer may consecutively run a dead-load analysis, a live-load analysis, a wind-load analysis, etc.; a program option then allows him to ask for any linear combination of these loadings he desires. Designers who have manually checked all the group loadings required by the AASHO specifications at their various unit stresses will appreciate this feature.

Further research in the area of linear analysis of planar structures does not appear warranted at this time. Future areas of research will be in nonlinear analysis and extensions to three-dimensional structures.

It is recommended that designers who have need for this program code some simple example problems in order to become familiar with its use. In addition, informal training sessions conducted by the research personnel would be extremely useful in implementing this work for immediate use by the Texas Highway Department.

.

CHAPTER 1. INTRODUCTION

Statement of Problem

Many highway structures such as bridge bents and freeway overpasses are designed as plane frames. These structures may be composed of nonprismatic elastically restrained members and may be subjected to several complicated loading conditions. A thorough elastic analysis is economically feasible only with the aid of a digital computer program that is both versatile and convenient.

Most existing frame analysis programs are difficult or impossible to use for such real problems. Three frame solutions (Refs 2, 5, and 7) which incorporate the versatility of the discrete-element beam-column model (Refs 8 and 9) have been reported previously. References 5 and 7 use an alternatingdirection iterative solution for the simultaneous equations which occur in the analysis. Recent developments in the direct solution of simultaneous equations (Ref 3) have made ADI solutions relatively less attractive on the present generation of computers. In addition, the solutions found in Refs 5 and 7 are restricted to rectangular frames.

Reference 2 gives a direct solution for linearly elastic frames and also permits an iterative investigation of the interaction of axial loads and lateral displacements. This solution while more versatile than previous ones still does not provide the designer with the convenience needed for a routine linear analysis, i.e., it allows members of the frame to be at any angle relative to the frame coordinate system, but it requires an orthogonal grid with intersections at all joints.

Purpose of Study

The primary purpose of this study is to develop a computer solution for plane frames that has the maximum convenience for the user consistent with generality of member arrangement and loading. The program is intended for routine use in a design office and has the following distinguishable features:

1

- (1) Input of both regular and irregular frame geometries is simple and quick.
- (2) Members may be either rigidly connected or pinned to joints.
- (3) Loads and elastic restraints may act both normal and parallel to members and may be input in the most convenient coordinate system.
- (4) Member stiffness properties and loadings may be input in normal engineering terms rather than as concentrated values at discrete stations.
- (5) Solutions of dead, live, wind, and other loads may be multiplied by appropriate load factors and superimposed to satisfy code loading requirements.

A secondary purpose of this report is to develop a solution of the frame members by the direct stiffness method (Ref 6) using a modification of the discrete-element model previously reported.

Assumptions and Limitations of the Proposed Solution

The solution developed is for the linearly elastic analysis of plane frames subjected to static inplane loads and displacements and has the following restrictions of conventional plane frame analysis:

- (1) Members are represented as straight-line elements intersecting at joints of infinitesimal size and are either rigidly connected or pinned to the joints.
- (2) Members are made of a linearly elastic material.
- (3) Displacements and deformations are small enough that the equilibrium equations can be formulated on the undeformed structure. Thus, the interaction of axial loads and lateral displacements is neglected.
- (4) Shearing deformations are neglected.

Outline of Report

The conventional theory of the direct stiffness method is presented in Chapter 2, and the method is applied to develop the joint equilibrium equations for the frame solution. Chapter 3 develops the equilibrium equations for the frame members by the direct stiffness method and discusses how they are used to obtain the member properties required for the frame solution and the member results. In Chapter 4 the equations needed to internally transform the engineering data into discretized station values are given.

The organization of and the input for the computer program are discussed in Chapter 5. Several example problems are presented in Chapter 6 to illustrate the features of the program. The results of this study are given in Chapter 7.

Appendix 1 gives a theoretical justification of the discrete-element model developed in the report. The remaining appendices have the input guides, flow charts, FORTRAN notation, FORTRAN listing of the program, and input and selected output for the example problems. This page replaces an intentionally blank page in the original. -- CTR Library Digitization Team

CHAPTER 2. LINEAR MATRIX ANALYSIS OF STATICALLY LOADED PLANE FRAMES

General Theory

Most methods of structural analysis can be classified as either displacement or force methods. The classification is based on whether the basic unknowns are displacements^{*} or forces^{**}. The force or flexibility method has advantages for certain structures but is not as easy to formulate in general terms as the displacement method. Hence, the displacement or the stiffness method is the only one considered in this report.

For the purpose of a stiffness analysis, a structure may be visualized as a group of elements connected at a finite number of nodal points. Each nodal point can undergo one or more pertinent displacements. For each of these displacements, there is a corresponding force. A force and a displacement are said to correspond if they act at the same nodal point, have the same line of action, and their product has the units of work. The total number of nodal point displacements for a structure is said to be the degree of kinematic indeterminacy or the number of degrees of freedom of the structure.

The elastic analysis of a statically loaded structure is basically a problem in satisfying simultaneously four sets of conditions. The governing conditions are the equations of nodal point equilibrium, compatibility of nodal point displacement, any boundary conditions applied at the nodal points, and the elements force-displacement relations. It is assumed that the forcedisplacement relations used for the elements insure that equilibrium, compatibility, any boundary conditions applied to the elements, and the constitutive laws for the element are satisfied continuously throughout the element.

* Throughout this report, the word "displacement" should be considered to mean either a translation or a rotation.

5

^{**} Throughout this report, the word "force" implies either a translational force or a moment.

In many cases some approximation is actually made in developing the forcedisplacement relations as discussed in Chapter 3. The direct stiffness method, as described by Martin (Ref 6) is the most widely used technique for applying these four governing conditions to obtain the structures equilibrium equations.

A direct stiffness analysis of a structure can be separated somewhat arbitrarily into nine steps as outlined below. The general method is independent of the type of structure to which it is applied. Note that in the outline, the word matrix is not mentioned. This is done to emphasize that the basic ideas are not dependent on matrix algebra. However, matrix algebra is a powerful tool that enables the method to be developed concisely and implemented on a digital computer with ease.

Outline of the Direct Stiffness Method

- (1) Select nodal point displacements that insure nodal point compatibility is satisfied.
- (2) Calculate the force-displacement equations for all elements in their element coordinate systems.
- (3) Transform these equations into the structure coordinate system.
- (4) Sum up the nodal point forces corresponding to each nodal point displacement from the equations developed in Step 3. This gives the nodal point equilibrium equations in terms of element properties, nodal point forces, and nodal point displacements.
- (5) Modify the equations as necessary for support (displacement type boundary) conditions at the nodal points.
- (6) Solve the equations developed in Step 5 for the nodal point displacements. For the usual assumption of linearly elastic elements and small displacements, the equations are a set of linear simultaneous equations.
- (7) Transform the nodal point displacements into element displacements.
- (8) Solve for element forces from the force-displacement equations of Step 2.
- (9) Solve for nodal point reactions and check nodal point equilibrium.

The direct stiffness method, as outlined above, will be applied to a plane frame to obtain a solution for the joint (nodal point) displacements in the remainder of this chapter. The solutions of the individual frame members (elements) needed for the frame solution is accomplished by another application of the direct stiffness method to a general frame member in Chapter 3.

6

Plane Frame Definition

Consider a plane frame as shown in Fig 1. It is assumed that the frame is composed of members that may be treated as straight-line elements. All of the elements lie in a plane and all loads and displacements occur in that plane, which for convenience is taken to be the x-y plane of a right-hand Cartesian coordinate system.

The end of a member or the intersection of two or more members forms a joint and this joint is assumed to be rigid and to have negligible dimensions. A member may be either rigidly connected or pinned to the joint. When a member is rigidly connected to a joint, it and all other members also rigidly connected to the joint rotate through the same angle and transmit moment to one another. When a member is pinned to a joint, it is free to rotate independently of the joint and other members intersecting at that joint. Thus, no moment is transferred from a pinned-end member to any member at the joint.

Joint (Nodal Point) Displacements

Each joint (i) will in general have three degrees of freedom, \widetilde{W}_{i}^{1} , \widetilde{W}_{i}^{2} , and \widetilde{W}_{i}^{3} as shown in Fig 1. Translational displacements \widetilde{W}_{i}^{1} and \widetilde{W}_{i}^{2} must be equal (compatible) for all members intersecting at a joint. The rotational displacement may not be the same for all members at a joint, since some or all of the members may be pinned to the joint. Hence \widetilde{W}_{i}^{3} is defined as being the rotation of the joint, and the pin is assumed to be a part of the member^{*} occurring at an infinitesimal distance inside the member. Thus, \widetilde{W}_{i}^{3} is equal (compatible) for all members intersecting at a joint. \widetilde{W}_{i}^{1} , \widetilde{W}_{i}^{2} , and \widetilde{W}_{i}^{3} compose a vector $\{\widetilde{W}_{i}\}$ where $\{\widetilde{W}_{i}\}$ is a (3×1) matrix of structure displacements measured in structure coordinates.

A frame with N joints has a structure displacement vector $\{\widetilde{W}\}$ where $\{\widetilde{W}\}$ is a (3N × 1) matrix of structure displacements measured in structure coordinates. $\{\widetilde{W}\}$ then is composed of N submatrices $\{\widetilde{W}_{\underline{i}}\}$. The basic equation of nodal point compatibility is

$$\left\{\widetilde{W}_{i}\right\} = \left\{\overline{W}_{i}\right\}_{k}$$
(2.1)

The special force-displacement equations needed for members with pinned ends are discussed in the next section.

Fig 1. Plane frame.

(a) Forces.

(b) Displacements.

Fig 2. Prismatic, uniformly loaded plane frame member.

where

 $\left\{ \overline{W}_{i} \right\}_{k}$ = (3 × 1) matrix of member-end-displacements measured in structure coordinates for member k which has one of its joints at joint i.

Member (Element) Force-Displacement Equations

Consider a prismatic member as shown in Fig 2. Member (k) has its own local right-hand Cartesian coordinate system x'-y'-z'. The members x'-axis is directed along the members centroidal axis. To satisfy the assumption of planar behavior, the members y'-axis and z'-axis must be the members principle axes and the y'-axis must lie in the structure x-y plane. All member loads and restraints must also act in the x-y plane.

The prismatic member is assumed to have only uniform loads $q_{y'x'}$ and $q_{x'x'}$ acting on its full length as shown in Fig 2. The reason for the double subscripting will be discussed in Chapter 4. Neglecting the effect of shear-ing deformations and finite displacements, the following force-displacement equation (Ref 4) is derivable.

$$\begin{bmatrix} F_{1}^{1} \\ F_{1}^{2} \\ F_{1}^{3} \\ \hline F_$$

- A = cross-sectional area of the member,
- E = modulus of elasticity,
- L = length of member, and
- I = moment of inertia of cross-section about z'-axis.

The forces F, loads q, and displacements W are defined in Fig 2. In matrix notation, Eq 2.2 may be expressed as

$$\left\{F\right\}_{k} = \left[K\right]_{k} \left\{W\right\}_{k} + \left\{FF\right\}_{k}$$
(2.3)

where

All of the above are for member k derived in the members coordinate system.

For nonprismatic members or nonuniform loads, the member-force-displacement equations can still be expressed in matrix form by Eq 2.3, but $\begin{bmatrix} K \end{bmatrix}_k$ and $\{FF\}$ will not be the same as in Eq 2.2.

In general, ${FF}$ is the matrix of fixed-end-forces for member k and k can be found by working a fixed-end-member problem.

10

A typical element of $\begin{bmatrix} K \end{bmatrix}_k$ is K_{pq} . The p represents the pth row and q represents the qth column of $\begin{bmatrix} K \end{bmatrix}_k$. The range of p and q is from 1 to 6. For a linearly elastic member, K_p represents the force corresponding to the pth displacement due to a unit value of the qth displacement. Thus, the qth column of $\begin{bmatrix} K \end{bmatrix}_k$ is the collection of member-end-forces due to a unit value of the qth displacement. This is illustrated for $(q = 2 \text{ and } W_i^2 = 1)$ in Fig 3.

Chapter 3 presents the discrete-element technique for analyzing nonprismatic or nonuniformly loaded members and obtaining $\begin{bmatrix} K \end{bmatrix}$ and $\begin{cases} FF \\ FF \end{cases}$. In the rest of this chapter, it is assumed that they have been found correctly and no distinction is made between prismatic and nonprismatic members.

Members with pinned ends are treated as follows in order to maintain compatibility of rotational displacements at a joint. The pin is assumed to be located just inside the member at a negligible distance from the joint. Special stiffness matrices $\begin{bmatrix} K \end{bmatrix}_k$ and fixed-end-force matrices $\{FF\}_k$ will be used for the kth member. Reference 4 gives these matrices for prismatic members and a solution technique to develop them for other members is given in Chapter 3.

Since forces will be superimposed separately at each joint, it is convenient to partition $\begin{bmatrix} K \end{bmatrix}_k$, $\{F\}_k$, and $\{FF\}_k$ as suggested by the dashed k lines in Eq 2.2. This then gives

$$\begin{bmatrix} \bar{F}_{i} \\ - \\ F_{j} \end{bmatrix}_{k} = -\begin{bmatrix} K_{ii} & K_{ij} \\ - \\ K_{ji} & K_{jj} \end{bmatrix}_{k} \cdot \begin{bmatrix} W_{i} \\ - \\ W_{j} \end{bmatrix}_{k} + \begin{bmatrix} FF_{i} \\ - \\ FF_{j} \end{bmatrix}_{k}$$
(2.4)

where

$${F_i}_k = (3 \times 1)$$
 matrix of member-end-forces at joint i,
 $\begin{bmatrix} K_{ii} \end{bmatrix}_k = (3 \times 3)$ member stiffness matrix which represents the
forces at i due to unit displacements at i,

 $\begin{bmatrix} K_{ij} \end{bmatrix}_{k} = (3 \times 3)$ member stiffness matrix in member coordinates which represents the forces at i due to unit displacements at j,

$$\left\{ W_{i} \right\}_{k}$$
 = (3 × 1) matrix of member displacements at joint i, and
 $\left\{ FF_{i} \right\}_{k}$ = (3 × 1) matrix of member fixed-end-forces at joint i.

All of the above are for member k derived in the members coordinates. The matrices on the second row of Eq 2.4 are defined as above except i and j are interchanged.

Equation 2.4 represents two matrix equations, the first of which is

$$\left\{ F_{i} \right\}_{k} = \left[K_{ii} \right]_{k} \left\{ W_{i} \right\}_{k} + \left[K_{ij} \right]_{k} \left\{ W_{j} \right\}_{k} + \left\{ FF_{i} \right\}_{k}$$
 (2.5)

Equation 2.5 gives the member-end-forces acting at joint i in member coordinates. The forces and displacement in Eq 2.5 must be expressed in structure coordinates before $\{F_i\}$ can be added to other forces which are acting at the joint.

<u>Transformation of Member (Element) Force-Displacement</u> <u>Equations into Structure Coordinates</u>

The transformation at joint i, for member k , of member displacements in structure coordinates $\{\overline{W}_i\}_k$ to member displacement in member coordinates $\{W_i\}_k$ is given by

$$\left\{ W_{i} \right\}_{k} = \left[T \right]_{k} \left\{ \overline{W}_{i} \right\}_{k}$$
(2.6)

The transformation matrix for member k, $\begin{bmatrix} T \\ k \end{bmatrix}$, is given by Eq 2.7 (Ref 4).

$$\begin{bmatrix} T \end{bmatrix}_{k} = \begin{bmatrix} \alpha & \beta & 0 \\ -\beta & \alpha & 0 \\ 0 & 0 & 1 \end{bmatrix}$$
(2.7)
where

 α = cosine of angle between the x'-axis and x-axis, and β = cosine of angle between the x'-axis and y-axis.

Similarly, the transformation of member forces in structure coordinates $\{\widetilde{F}_i\}_k$ to member forces in member coordinates $\{F_i\}_k$ is given by Eq 2.8

$$\left\{\mathbf{F}_{i}\right\}_{k} = \left[\mathbf{T}\right]_{k} \left\{\overline{\mathbf{F}}_{i}\right\}_{k}$$
(2.8)

where for member k

 ${F_i}_k = (3 \times 1)$ matrix of member-end-forces at joint i in member coordinates,

 $\left\{ \overline{F}_{i} \right\}_{k}$ = (3 × 1) matrix of member-end-forces at joint i in structure coordinates, and

$$\begin{bmatrix} T \end{bmatrix}_k$$
 = the previously defined coordinate transformation matrix.

Since $\begin{bmatrix} T \end{bmatrix}_k$ is an orthogonal matrix, it possesses the special properties that its transpose $\begin{bmatrix} T \end{bmatrix}_k^t$ is also its inverse $\begin{bmatrix} T \end{bmatrix}_{k}^{-1}$ and that the product of $\begin{bmatrix} T \end{bmatrix}_k$ and $\begin{bmatrix} T \end{bmatrix}_{k}^t$ in any order is equal to the identity matrix $\begin{bmatrix} I \end{bmatrix}$. Therefore

$$\left\{ \overline{W}_{i} \right\}_{k} = \left[T \right]_{k}^{L} \left\{ W_{i} \right\}_{k}$$
(2.9)

and

$$\left\{\overline{F}_{i}\right\}_{k} = \left[T\right]_{k}^{t} \left\{F_{i}\right\}_{k}$$
(2.10)

Substituting Eq 2.6 into Eq 2.5 for $\{W_i\}_k$ and $\{W_j\}_k$, premultiplying both sides of Eq 2.5 by $[T]_k^t$ and using Eq 2.10 gives

$$\left\{ \overline{F}_{i} \right\}_{k} = \left[T \right]_{k}^{t} \left[K_{ii} \right]_{k} \left[T \right]_{k} \left\{ \overline{w}_{i} \right\}_{k} + \left[T \right]_{k}^{t} \left[K_{ij} \right]_{k} \left[T \right]_{k} \left\{ \overline{w}_{j} \right\}_{k}$$

$$+ \left[T \right]_{k}^{t} \left\{ FF \right\}_{k}$$

$$(2.11)$$

$$\begin{bmatrix} \overline{K}_{ii} \end{bmatrix}_{k} = \begin{bmatrix} T \end{bmatrix}_{k}^{t} \begin{bmatrix} K_{ii} \end{bmatrix}_{k} \begin{bmatrix} T \end{bmatrix}_{k}$$
(2.12)

$$\begin{bmatrix} \tilde{\mathbf{K}}_{ij} \end{bmatrix}_{\mathbf{k}} = \begin{bmatrix} \mathbf{T} \end{bmatrix}_{\mathbf{k}}^{\mathbf{t}} \begin{bmatrix} \mathbf{K}_{ij} \end{bmatrix}_{\mathbf{k}} \begin{bmatrix} \mathbf{T} \end{bmatrix}_{\mathbf{k}}$$
(2.13)

$$\left\{\overline{FF}_{i}\right\}_{k} = \left[T\right]_{k}^{t} \left\{FF_{i}\right\}_{k}$$

$$(2.14)$$

then for member k

- $\begin{bmatrix} \overline{K}_{ii} \end{bmatrix}_{k} = (3 \times 3)$ member stiffness matrix in structure coordinates which represent the forces at i due to unit displacements at i,
- $\begin{bmatrix} \overline{K}_{ij} \end{bmatrix}_{k} = (3 \times 3)$ member stiffness matrix in structure coordinates which represents the forces at i due to unit displacements at j, and

$$\left\{\overline{FF}_{i}\right\}_{k}$$
 = (3 × 1) matrix of member-fixed-end-forces in structure coordinates.

Then Eq 2.11 can be rewritten as

$$\left\{\overline{F}_{i}\right\}_{k} = \left[\overline{K}_{ii}\right]_{k} \left\{\overline{W}_{i}\right\}_{k} + \left[\overline{K}_{ij}\right]_{k} \left\{\overline{W}_{j}\right\}_{k} + \left\{\overline{FF}_{i}\right\}_{k}$$
(2.15)

To satisfy the compatibility requirement, Eq 2.1 can be substituted into Eq 2.15 for $\{\overline{w}_i\}_{k}$ and $\{\overline{w}_j\}_{k}$, to give

$$\left\{\overline{F}_{i}\right\}_{k} = \left[\overline{K}_{ii}\right]_{k} \left\{\widetilde{W}_{i}\right\} + \left[\overline{K}_{ij}\right] \left\{\widetilde{W}_{j}\right\} + \left\{\overline{FF}_{i}\right\}_{k}$$
(2.16)

Summation of Joint (Nodal Point) Forces

Each joint must be in static equilibrium due to the forces imparted to it by each of the M members acting there, any applied joint forces, and any support reactions. The effect of the support reactions will be considered in the next section. The applied joint forces \widetilde{P}_i^1 , \widetilde{P}_i^2 , and \widetilde{P}_i^3 at joint i represent a vector $\{\widetilde{P}_i\}$ (see Fig 1)

where

$$\left\{ \widetilde{P}_{i} \right\} = (3 \times 1)$$
 matrix of applied joint forces at joint i.

Thus, temporarily neglecting the support reactions at joint i, $\{\widetilde{P}_i\}$ is equal to the sum of $\{\widetilde{F}_i\}$ from Eq 2.16 for all M members.

$$\left\{ \widetilde{\mathbf{P}}_{i} \right\} = \left(\sum_{k=1}^{M} \left[\overline{\mathbf{K}}_{ii} \right]_{k} \right) \left\{ \widetilde{\mathbf{W}}_{i} \right\} + \sum_{k=1}^{M} \left(\left[\overline{\mathbf{K}}_{ij} \right]_{k} \left\{ \widetilde{\mathbf{W}}_{j} \right\} \right)$$

$$+ \sum_{k=1}^{M} \left\{ \overline{\mathbf{FF}}_{i} \right\}_{k} (2.17)$$

Equation 2.17 can be rearranged to have all loads on the right-hand side as follows:

$$\left(\begin{array}{c} M \\ \Sigma \\ k=1 \end{array} \left[\overline{K}_{ii} \right]_{k} \right) \left\{ \widetilde{W}_{i} \right\} + \begin{array}{c} M \\ k=1 \end{array} \left(\left[\overline{K}_{ij} \right]_{k} \cdot \left\{ \widetilde{W}_{j} \right\} \right)$$
$$= \left\{ \widetilde{P}_{i} \right\} - \begin{array}{c} M \\ \Sigma \\ k=1 \end{array} \left\{ \overline{FF}_{i} \right\}_{k}$$
(2.18)

Equation 2.18 can be applied now to all N joints (i = 1,N) to form the structure equilibrium equations which can be expressed as

$$\begin{bmatrix} \widetilde{K} \end{bmatrix} \cdot \{ \widetilde{W} \} = \{ \widetilde{F} \}$$
 (2.19)

where

 $\begin{bmatrix} \tilde{K} \end{bmatrix} = (3N \times 3N) \text{ structure stiffness matrix,} \\ \{ \widetilde{W} \} = (3N \times 1) \text{ structure displacement matrix,} \\ \{ \widetilde{F} \} = (3N \times 1) \text{ structure load matrix.} \\ \begin{bmatrix} \infty \end{bmatrix}$

Clearly $\begin{bmatrix} \widetilde{K} \end{bmatrix}$ can be partitioned into N²(3 x 3) submatrices $\begin{bmatrix} \widetilde{K}_{ij} \end{bmatrix}$ and from Eq 2.18.

$$\begin{bmatrix} \widetilde{K}_{ii} \end{bmatrix} = \sum_{k=1}^{M} \begin{bmatrix} \overline{K}_{ii} \end{bmatrix}_{k}$$
(2.20)

and

$$\begin{bmatrix} \tilde{K}_{ij} \end{bmatrix} = \begin{bmatrix} \bar{K}_{ij} \end{bmatrix}_{k} \qquad i \neq j \qquad (2.21)$$

Thus the structure stiffness matrix is easily composed from the individual member stiffness matrices expressed in structure coordinates. Similarly the (3×1) load matrix at the ith joint $\{\widetilde{F}\}$ is given by Eq 2.18 as,

$$\left\{\widetilde{\mathbf{F}}_{\mathbf{i}}\right\} = \left\{\widetilde{\mathbf{P}}_{\mathbf{i}}\right\} - \sum_{k=1}^{M} \left\{\overline{\mathbf{FF}}_{\mathbf{i}}\right\}_{k}$$
(2.22)

Joint Supports (Displacement Type Boundary Conditions)

Suppose that any joint i has three linearly elastic support springs, with spring constants \tilde{S}_{i}^{1} , \tilde{S}_{i}^{2} , and \tilde{S}_{i}^{3} , as shown in Fig 1. Any of these can be zero as a lower limit and approach infinity as an upper limit. If a joint undergoes displacement during the application of loads, then support reactions will be generated equal to the negative of the displacements times the corresponding spring constants. Clearly these reactions must be considered in writing the joint equilibrium equations. If these terms are added to equations, the effect on $\begin{bmatrix} \widetilde{K} \end{bmatrix}$ is to add the corresponding spring term to the diagonal of the matrix.

The effect of the other matrix terms becomes negligible as the spring term becomes very large compared to the other terms in any row of $\begin{bmatrix} \widetilde{K} \end{bmatrix}$. Similarly the load term for that row becomes negligible.

Thus, a zero displacement can be obtained by specifying a very large spring restraint. Likewise, a specified displacement may be obtained by specifying a large spring restraint and a correspondingly large joint force equal to the desired displacement times the spring restraint.

Handling specified displacements in this way allows both real problems where supports have some reasonable value of restraint and other problems with infinitely stiff supports to be solved by the same technique.

When all members at a joint are hinged to the joint, the rotational stiffness at the joint is zero. This causes a singular set of equations for which the solution process as discussed in the next section will either cause an arithmetic error on the computer due to the attempt to divide by zero or give extremely large displacements.

One method of solving structures with such pinned joints is to renumber the joint equilibrium equations allowing only two degrees of freedom at the pinned joints. This loses much of the generality built into the equations of this chapter. Instead, the present computer program places a unit value on the diagonal of $\begin{bmatrix} \tilde{K} \end{bmatrix}$ and a very large value in the load matrix. This gives, then, a very large displacement for the rotation of such a joint which indicates that it is undefined.

Similarly, when a joint is deleted in a series of problems by removing all the members intersecting at the joint, all three of the displacements of such a joint are undefined and the program handles such a joint the same way. Unit values are placed on the diagonal for all three of the zero stiffnesses and three large values are placed in the load matrix for the three undefined displacements.

Since for both the pinned joint and the joint with all members deleted setting the displacements equal to a large value has no physical effect on the structure, the rest of the solution is valid. However, the large displacements should occur only for the rotation of joints with all members pinned or a joint that is deleted. Any other large displacements are an indication that an unstable or nearly unstable structure has been described. The user will be aware that he has such a joint so no misunderstanding of the results should occur.

Solution of Joint (Nodal Point) Equilibrium Equations

The equations developed in the preceeding section are a system of linear-simultaneous equations which can be solved efficiently using a recursioninversion process previously developed (Ref 3).

The solution of Ref 3 considers the banding of the stiffness matrix inherent in structural problems. It also takes advantage of the symmetry of the structure stiffness matrix.

The second and succeeding solutions of a structure (for additional load cases) are obtained in far less time than the initial solution. This is possible since the stiffness matrix for a linearly-elastic structure is independent of the loading, therefore the elimination process need not be repeated after the first solution.

Member (Element) Displacements from Joint (Nodal Point) Displacements

Once joint displacements are found, the member displacements can be obtained from Eqs 2.6 and 2.1. Note that for a member with a pinned end this will give the displacement on the joint side of the pin (which is actually the joint displacement). However, as outlined in the next section, this will not affect the solution of member-end-forces.

Member (Element) Forces

For prismatic members with only uniform loads the member-end-forces can be found by using Eq 2.2 or for such members with pinned ends the special equations in Ref 4 can be used. For nonprismatic members or nonuniformly

loaded members, the member-end-forces can be found by the solution developed in Chapter 3. This solution can also be used for cases in which more complete output of forces and displacements throughout the member is desired.

Joint (Nodal Point) Reactions and Check of Joint Equilibrium Equations

Once the member-end-forces have been calculated, they can be converted to structure coordinates by Eq 2.10. With all supports specified as linearlyelastic springs the joint reactions can be found merely by multiplying the spring constants times the negative of the corresponding displacements. If the proper solution of the equilibrium equations has been found, the sum of the member-end-forces applied to the joint should equal the applied joint forces plus the joint reactions. Any difference between the joint forces and the member forces is an indication of the roundoff error developed in the solution of the equations. Generally this error (joint equilibrium error) will be a very small quantity.

There is one case in which the joint equilibrium error is not a valid indication of the accuracy of the solution. When a specified displacement is enforced at a joint by an artificially large restraint and a correspondingly large force the joint equilibrium error will be as many orders of magnitude less than the artificial load as the computer is inaccurate in subtracting two numbers. This is not an indication that the solution is in error but only that the estimate of the error is invalid. This occurs only when artificially large values are used to specify displacements and has never occurred on the CDC 6600 with approximately 15 significant digits for any physical values of restraint and load.

Superposition Solution

Under sufficiently small loads structures behave in a linear manner. Thus the results of several linear solutions may be stored and combined by simple superposition to form any linear combination of loadings desired. Naturally the designer must check the results to insure that the stresses in the structure are small enough for the superposition solution to be valid.

CHAPTER 3. NEW DISCRETE-ELEMENT TECHNIQUE FOR SOLUTIONS OF GENERAL FRAME MEMBERS

As previously discussed, solutions for the members stiffness matrix $\begin{bmatrix} K \\ k \end{bmatrix}_k$ and the members fixed-end-force matrix $\{FF\}_k$ are required for nonprismatic, elastically restrained, and nonuniformly loaded members. The discrete-element formulation from Ref 9 was used in Ref 2 to obtain $\begin{bmatrix} K \\ k \end{bmatrix}_k$ and $\{FF\}_k$. This discrete-element model does not provide for loads or restraints acting parallel to the member. This causes problems in coding frames with members that are not horizontal but have significant vertical (gravity) loads. Frames with friction piles are also difficult to input.

The basic element of the discrete-element beam column model (Ref 9) is a rigid bar with one degree of freedom at each end (lateral displacement). If the bar were made axially deformable it would have four degrees of freedom (a lateral and an axial displacement at each end). The stiffness or equilibrium equations for a member composed of a number of such elements connected by rota-tional springs could be formulated in the same manner as was done for the discrete-element in Ref 9. However, the member equilibrium equations are developed formally by the direct stiffness method (Ref 6) using a modification of the discrete-element technique proposed herein.

Frame Member with Discretized Effects

A general frame member is shown in Fig 4(a). The member is general in that at any station i, forces \tilde{p}_1^1 , \tilde{p}_1^2 , and \tilde{p}_1^3 may act, elastic restraints \tilde{s}_1^1 , \tilde{s}_1^2 , and \tilde{s}_1^3 may exist, and changes in cross-sectional properties may occur. Each continuous element i between stations i-1 and i is assumed to have a linear variation in cross-sectional properties. The term AE_i is the axial rigidity of the element at mid-element and EI_i is the flexural rigidity of the element at the midpoint. The terms A, E, and I are as previously defined. The member is further generalized in Chapter 4 to make it more convenient for the user by allowing loads, restraints, and changes in cross-section

(a) Frame member with discretized loads, restraints, and stiffness changes.

(b) Mechanical model of element i.

.

Fig 4. Frame member and discrete-element representation of one of its continuous elements.

to occur at any point in the member. Distributed values of load and restraint are permitted and loads may be input in either frame or member coordinates. Chapter 4 presents the method of handling such effects, therefore, in this chapter the discrete station values are assumed to be available.

Application of the Direct Stiffness Method to Frame Members

The frame member may now be considered to be a structure composed of m elements, which for convenience are numbered from 2 to m+1 in Fig 4a. Each of the m+1 stations (nodal points) of the frame member has three displacements (axial displacement \widetilde{w}_1^1 , lateral displacement \widetilde{w}_i^2 , and rotational displacement \widetilde{w}_i^3). These displacements should be equal for both elements intersecting at a station. Thus, there is no difference between the frame analysis and the member analysis other than some simplifications because of the simplified geometry of the member. (The frame member's axes x'-y'-z' and the element's axes x"-y"-z" are parallel as shown in Fig 4a, hence no transformation of coordinates is required.) This means no distinction need be made between properties measured in element coordinates and properties measured in the frame member's coordinates. Therefore, the element stiffness matrix can be derived with reference to its own coodinates and used in Eq 2.18.

Discrete-Element Model

The stiffness matrix for a continuous element with linearly varying stiffness properties could be derived, but to work with it would be difficult. Instead, the stiffness matrix of the element will be derived for the discreteelement shown in Figs 4b and 4c, and in Appendix 1 it is shown that the discrete-element model is an adequate representation of the continuous element. That is to say that, as the number of elements used increases, the answers obtained by the discrete-element approaches as a limit the "exact" solution.

A mechanical model of the discrete-element whose length is 2h is shown in Fig 4b. It is composed of two rigid end blocks, two rotational springs with spring constants EI_i/h and a rigid piston with an axial spring whose spring constant is $\text{AE}_i/2h$. The term EI_i is the product of the modulus of elasticity and the moment of inertia at the center of the continuous element. The term AE_i is the product of the cross-sectional area and the modulus of elasticity at the center of the continuous element. The mechanical model of Fig 4b may be shown more conveniently as a discrete-line element model in Fig 4c. There the element is composed of three one-dimensional bars which are rigid in bending and connected by rotational springs with spring constants EI_i/h . The end bars are axially rigid but the center bar of length h is axially deformable and has an axial rigidity of $AE_i/2$. The two models are mathematically equivalent and hereafter the discrete-line element model will be shown for convenience and will be referred to as the discrete-element model.

Element Stiffness Matrix

The discrete-element i has three degrees of freedom at each station and will have a (6×6) element stiffness matrix $[k]_i$, which relates forces and displacement at stations i and i-1. As mentioned in Chapter 2, the qth column of a stiffness matrix is the set of reactions corresponding to the displacements due to a unit value of the qth displacement. This is illustrated in Fig 5 for element i, q = 4, 5, and 6.

For each of the six unit displacements, the discrete angle changes and changes in length of the deformable bar may be found geometrically. The internal spring moments and the axial force can then be computed. Next a freebody analysis can be made and the forces acting on the ends of the element can be found. These forces are the desired stiffness terms. Assuming negligible displacements, the freebody analysis can be made on the undeformed element, thus neglecting the effect of the secondary moment caused by axial forces acting on lateral displacements. This secondary moment could be included in the analysis but would then require a nonlinear solution since, in general, the effect of axial forces is not linear. Therefore, in the development of this design oriented linear analysis program it is not considered. However, in the future it probably will be incorporated in nonlinear studies.

In Fig 5a (q = 4 and \widetilde{w}_{i}^{1} = 1) the axially deformable bar extends one inch, thus the force T_{i} in the bar is given by Eq 3.1

$$T_{i} = \frac{AE_{i}(1)}{2h} = \frac{AE_{i}}{2h}$$
 (3.1)

(a) Fourth column of element stiffness matrix.

(b) Fifth column of element stiffness matrix.

(c) Sixth column of element stiffness matrix.

Fig 5. Unit displacements at station i on element i.

For equilibrium of forces parallel to x''

$$k_{44} = \frac{AE_i}{2h}$$
(3.2)

and

$$k_{14} = \frac{-AE_i}{2h}$$
(3.3)

All other forces are zero because of the assumed small displacements. In Fig 5b (q = 5 and \tilde{w}_i^2 = 1) concentrated curvatures ψ_1 and ψ_2 are developed at the spring locations. For the unit displacement shown in Fig 5b

$$\Psi_1 = \frac{1}{h} \tag{3.4}$$

$$\Psi_2 = \frac{-1}{h} \tag{3.5}$$

The internal moments corresponding to Ψ_1 and Ψ_2 are M_1 and M_2 where

$$M_{1} = \frac{EI_{i}\Psi_{1}}{h} = \frac{EI_{i}}{h^{2}}$$
(3.6)

$$M_{2} = \frac{EI_{i}\Psi_{2}}{h} = \frac{-EI_{i}}{h^{2}}$$
(3.7)

^{*} The sign of the curvature and corresponding moment is positive if it produces compression on the positive y'' side of the member.

Shears * V₁ and V₂ will be developed at the two spring locations and can be found from a freebody analysis of the axially deformable center bar.

$$V_1 = \frac{(M_2 - M_1)}{h} = -\frac{2EI_1}{h^3}$$
 (3.8)

$$V_2 = -V_1 = \frac{2EI_1}{h^3}$$
 (3.9)

Summing forces and moments on freebodies of the two end bars yields

$$\begin{vmatrix} k_{15} \\ k_{25} \\ k_{25} \\ k_{35} \\ k_{35} \\ k_{45} \\ k_{55} \\ k_{65} \\ \end{vmatrix} = \begin{vmatrix} \frac{2EI_{1}}{h^{3}} \\ -\frac{2EI_{1}}{h^{2}} \\ 0 \\ \frac{2EI_{1}}{h^{3}} \\ -\frac{2EI_{1}}{h^{2}} \\ -\frac{2EI_{1}}{h^{2}} \end{vmatrix}$$
(3.10)

In Fig 5c (q = 6 and \widetilde{w}_{i}^{3} = 1) concentrated curvatures Ψ_{1} and Ψ_{2} are developed where

$$\Psi_1 = -\frac{1}{2}$$
(3.11)

^{*} Positive shear acts in the direction of positive y' on the face of the freebody closest to the member axis.

$$\Psi_2 = \frac{3}{2}$$
 (3.12)

hence

$$M_1 = -\frac{EI_1}{2h}$$
 (3.13)

$$M_2 = \frac{3EI_i}{2h}$$
(3.14)

and

$$V_1 = \frac{2EI_1}{h^2}$$
 (3.15)

$$V_2 = -\frac{2EI_1}{h^2}$$
 (3.16)

Summing forces and moments on the end bars yields

$$\begin{bmatrix} k_{16} \\ k_{26} \\ k_{36} \\ k_{46} \\ k_{46} \\ k_{56} \\ k_{66} \end{bmatrix} = \begin{bmatrix} 0 \\ \frac{2EI_i}{h^2} \\ \frac{1.5EI_i}{h} \\ 0 \\ -\frac{2EI_i}{h^2} \\ \frac{2.5EI_i}{h} \end{bmatrix}$$

.

(3.17)

•

Similarly, by applying unit displacements at i-1 the first three columns of the element stiffness matrix may be obtained. Thus,

$$\begin{bmatrix} \mathbf{A} \frac{\mathbf{E}_{i}}{2\mathbf{h}} & 0 & 0 & -\frac{\mathbf{A} \frac{\mathbf{E}_{i}}{2\mathbf{h}}}{\mathbf{h}^{3}} & 0 & 0 \\ 0 & \frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{3}} & \frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} & 0 & -\frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{3}} & \frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} \\ 0 & \frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} & \frac{2.5\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}} & 0 & -\frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} & \frac{1.5\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}} \\ -\frac{\mathbf{A} \frac{\mathbf{E}_{i}}{2\mathbf{h}}}{\mathbf{h}} & 0 & 0 & \frac{\mathbf{A} \frac{\mathbf{E}_{i}}{2\mathbf{h}}}{\mathbf{h}} & 0 & 0 \\ 0 & -\frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{3}} & -\frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} & 0 & \frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{3}} & -\frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} \\ 0 & \frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{3}} & -\frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} & 0 & \frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{3}} & -\frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} \\ 0 & \frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} & \frac{1.5\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}} & 0 & -\frac{2\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}^{2}} & \frac{2.5\mathbf{E}\mathbf{I}_{i}}{\mathbf{h}} \end{bmatrix}$$

The element end forces $\{f\}$ are related to the element end displacements $\{w\}_{i}$ as shown in Eq 3.19.

$$\left\{f\right\}_{i} = \left[k\right]_{i} \left\{w\right\}_{i} \tag{3.19}$$

The matrix $\begin{bmatrix} k \end{bmatrix}_i$ can be subdivided into four 3 by 3 submatrices as was done in Chapter 2 for $\begin{bmatrix} K \end{bmatrix}_k$:

Loads acting between the nodal points are transformed into equivalent nodal point loads, hence, no fixed-end-forces act as in Eq 2.3.

$$\begin{bmatrix} k \end{bmatrix}_{i} = \begin{bmatrix} k_{i-1,i-1} & | & k_{i-1,i} \\ \hline k_{i,i-1} & | & k_{i,i} \end{bmatrix}_{i}$$
(3.20)

where the submatrices are given by Eq 3.18.

Similarly, the element stiffness matrix for element i+1, which connects with element i at station i, can be divided into four 3 by 3 submatrices:

$$\begin{bmatrix} k \end{bmatrix}_{i+1} = \begin{bmatrix} \frac{k_{i,i} & | & k_{i,i+1} \\ \vdots & \vdots & \vdots \\ k_{i+1,i} & | & k_{i+1,i+1} \end{bmatrix}$$
(3.21)

The submatrices of Eq 3.21 are given by the terms in Eq 3.18 except AE_i is replaced by AE_{i+1} and EI_i is replaced by EI_{i+1} .

Substituting the appropriate submatrices from Eqs 3.20 and 3.21 into Eq 2.18 (M = 2) yields

$$\left(\begin{bmatrix} k_{i,i} \end{bmatrix}_{i} + \begin{bmatrix} k_{i,i} \end{bmatrix}_{i+1} \right) \left\{ \widetilde{w}_{i} \right\} + \begin{bmatrix} k_{i,i-1} \end{bmatrix}_{i-1} \left\{ \widetilde{w}_{i-1} \right\}$$
$$+ \begin{bmatrix} k_{i,i+1} \end{bmatrix}_{i+1} \left\{ \widetilde{w}_{i+1} \right\} = \left\{ \widetilde{p}_{i} \right\}$$
(3.22)

Substituting into Eq 3.22 the appropriate submatrices as given by Eq 3.18 and adding in the effect of the elastic restraints $\{\widetilde{s}_i\}$ gives

$$\left(\begin{bmatrix} \frac{AE_{i}}{2h} & 0 & 0 \\ 0 & \frac{2EI_{i}}{h^{3}} & -\frac{2EI_{i}}{h^{2}} \\ 0 & -\frac{2EI_{i}}{h^{3}} & \frac{2.5EI_{i}}{h} \end{bmatrix} + \begin{bmatrix} \frac{AE_{i+1}}{2h} & 0 & 0 \\ 0 & \frac{2EI_{i+1}}{h^{3}} & \frac{2EI_{i+1}}{h^{2}} \\ 0 & \frac{2EI_{i+1}}{h^{2}} & \frac{2.5EI_{i}}{h} \end{bmatrix} + \begin{bmatrix} 0 & \frac{2EI_{i+1}}{h^{3}} & \frac{2EI_{i+1}}{h^{2}} \\ 0 & \frac{2EI_{i+1}}{h^{2}} & \frac{2.5EI_{i+1}}{h} \end{bmatrix}$$

Summing up the matrices of Eq 3.23 and multiplying the first row by h and the second and the third rows by h^3 and rearranging yields

$$\begin{bmatrix} -\frac{AE_{i}}{2} & 0 & 0 \\ 0 & -2EI_{i} & -2hEI_{i} \\ 0 & 2hEI_{i} & 1.5h^{2}EI_{i} \end{bmatrix} \cdot \begin{bmatrix} \widetilde{w}_{i-1}^{2} \\ \widetilde{w}_{i-1}^{3} \\ \widetilde{w}_{i-1}^{3} \end{bmatrix}$$

$$+ \begin{bmatrix} \frac{AE_{i}+AE_{i+1}}{2} + \widetilde{s}^{1}h & 0 & 0 \\ 0 & 2(EI_{i}+EI_{i+1}) + \widetilde{s}^{2}_{i}h^{3} & 2h(EI_{i+1}-EI_{i}) \\ 0 & 2h(EI_{i+1}-EI_{i}) & 2.5h^{2}(EI_{i}+EI_{i+1}) + \widetilde{s}^{3}_{i}h^{3} \end{bmatrix} \cdot \begin{bmatrix} \widetilde{w}_{i}^{1} \\ \widetilde{w}_{i}^{2} \\ \widetilde{w}_{i}^{3} \end{bmatrix}$$

$$\begin{bmatrix} -\frac{AE_{i+1}}{2} & 0 & 0 \end{bmatrix} \begin{bmatrix} \widetilde{w}_{i+1}^{1} \end{bmatrix} \begin{bmatrix} \widetilde{p}_{i}^{1}h \end{bmatrix}$$

+ $\begin{bmatrix} 0 & -2EI_{i+1} & 2hEI_{i+1} \\ 0 & -2hEI_{i+1} & 1.5h^2EI_{i+1} \end{bmatrix}$ $\begin{bmatrix} \tilde{v}_{i+1}^2 \\ \tilde{v}_{i+1}^3 \end{bmatrix} = \begin{bmatrix} \tilde{p}_{i}^2h^3 \\ \tilde{p}_{i}^3h^3 \end{bmatrix}$ (3.24)

Equation 3.24 may be applied at the m+l nodal points to form the member equilibrium equation.* Since Eq 3.24 represents three scalar equations this will yield 3(m+l) simultaneous equations. These equations will be symmetric and have a band width of nine. Noting that the axial (\widetilde{w}^1) and lateral $(\widetilde{w}^2$ and $\widetilde{w}^3)$ displacements are uncoupled in Eq 3.24 the solution may be separated into m+l axial equations with a band width of three and 2(m+l) lateral equations with a band width of seven.

r

^{*} In order to apply Eqs 3.24, 3.25, 3.26, and 3.27 at nodal points i = 1 and i = m+1, fictious elements i = 1, and i = m+2 must be assigned zero stiffness.

The axial equations are given by the m+1 application of Eq 3.25

$$-\frac{AE_{i}}{2}\widetilde{w}_{i-1} + \left(\frac{AE_{i}}{2} + \frac{AE_{i+1}}{2} + \widetilde{s}_{i}^{1}h\right)\widetilde{w}_{i}^{i} - \frac{AE_{i+1}}{2}\widetilde{w}_{i+1}$$
$$= \widetilde{p}_{i}^{1}h \qquad (3.25)$$

The lateral equations are generated by m+1 applications of Eqs 3.26 and 3.27.

$$-(2EI_{i}) \tilde{w}_{i-1}^{2} - (2hEI_{i}) \tilde{w}_{i-1}^{3} + [2(EI_{i}+EI_{i+1}) + \tilde{s}_{i}^{2}h^{3}] \tilde{w}_{i}^{2}$$

$$+ [2h(EI_{i+1}-EI_{i})] \tilde{w}_{i}^{3} - (2EI_{i+1}) \tilde{w}_{i+1}^{2} + (2hEI_{i+1}) \tilde{w}_{i+1}^{3}$$

$$= \tilde{p}_{i}^{2}h^{3} \qquad (3.26)$$

$$(2hEI_{i}) \tilde{w}_{i-1}^{2} + (1.5h^{2}EI_{i}) \tilde{w}_{i-1}^{3} + [2h(EI_{i+1} - EI_{i})] \tilde{w}_{i}^{2}$$

$$+ [2.5h^{2}(EI_{i} + EI_{i+1}) + \tilde{s}_{i}^{3}h] \tilde{w}_{i}^{3} - (2hEI_{i+1}) \tilde{w}_{i+1}^{2}$$

$$+ (1.5h^{2}EI_{i+1}) \tilde{w}_{i+1}^{3} = \tilde{p}_{i}^{3}h^{3} \qquad (3.27)$$

Both the axial and lateral equations are easily solvable by the method in Ref 3.

Once the nodal point displacements have been found they may be substituted into Eq 3.19 to find the member-end-forces. The elastic support forces may be found by multiplying the spring constants times the negative of the nodal point displacements. Then the nodal point equilibrium error (the nodal point forces minus the element forces) may be calculated. This should be a negligible quantity except for the cases where a specified displacement is enforced by a large spring value and a correspondingly large force as discussed in Chapter 2.

Calculation of Member Fixed-End-Force Vector

The fixed-end-forces ${FF}_k$ for each nonprismatic or nonuniformly loaded member in the frame may be obtained by a discrete-element solution of the member. The member is subjected to all its member loads and elastic restraints and the end displacements are set equal to zero by using three large spring values at stations 1 and m+1. The end forces acting on the member at stations 1 and m+1 are the desired fixed-end-forces. The member-end-forces are essentially equal to the forces acting on the end elements of the member. However, when the member has a discretized load or elastic restraint at the end of the member, the member-end-force is equal to [(the element-end-force) - (the discretized load) + (the spring restraint) x (the element-end-displacement)].

For members with pinned ends, the rotational spring restraint is not set equal to a large value, thus leaving it free to rotate.

Calculation of Member Stiffness Matrix

The stiffness matrix $\begin{bmatrix} K \\ k \end{bmatrix}$ for each nonprismatic member in the frame may be obtained by six discrete-element solutions of the member. The member is subject to all its member elastic restraints and in turn six unit displacements are introduced corresponding to the three degrees of freedom at station 1 and station m+1.

The unit displacements are obtained by using three large springs at stations 1 and m+1 and six correspondingly large forces. Two of the solutions will be axial solutions as generated by Eq 3.24 and four of the solutions will be lateral solutions as generated by Eqs 3.25 and 3.26. The stiffness of the member does not change, hence the second axial solution and the second, third, and fourth lateral solutions do not require an elimination of the stiffness matrix. This saves a relatively small amount of time when considering the generation of a single member stiffness matrix, but when multiplied by a large number of members represents a sizable saving.

The member-end-forces at stations 1 and m+1 for each of the six solutions are the six columns of the member stiffness matrix. Actually only 13 of these 36 forces need be calculated and stored. Since $\begin{bmatrix} K \\ k \end{bmatrix}$ is always symmetrical, only 21 of its coefficients need be known. For a plane frame member subject to small displacements, 8 of these 21 will always be zero. Thus, only 13 member-end-forces need be calculated and stored to generate $\begin{bmatrix} K \\ k \end{bmatrix}$. The savings in calculations are insignificant but the savings in storage are considerable. Further reductions can be made if the member is assumed to have no elastic restraints acting between its ends. This was not done here to maintain the generality of the solution.

For pinned-end members, the corresponding rotational spring is not set to a large value and no moment is applied at the pinned end to enforce the unit rotation.

Calculation of Member Results

Once the frame joint displacements have been found by the solution of Chapter 2, they can be transformed into member-end-displacements. Then any frame member may be analyzed as a member subject to the member-end-displacements, applied member loads, and elastic restraints. The solution is similar to the solutions for $\begin{bmatrix} K \end{bmatrix}_{L}$ and $\{FF\}_{L}$ just discussed.

The displacements of all the stations will be found from such a solution. Then the spring support reactions may be found by multiplying the spring constants times the negative of the appropriate displacement. The element-endforces may be found from Eq 3.19. Then the nodal point equilibrium error may be evaluated.

Shears, moments, and axial forces in the member can now be found by statics at any point desired. The output used in the program is the average value of shear, moment, and axial force at every other nodal point.

Comparison of Finite-Element and Discrete-Element Methods

For an "exact" solution of a member, nodal point equilibrium, compatibility, and boundary conditions must be satisfied at the m+l nodal points (stations) and the force-displacement equations for the m elements must be satisfied. The exact force-displacement equations may not be known and are often obtained by an approximate method. The difference between the finite-element method and the discrete-element method is the way in which the elements forcedisplacement equations are approximated.

The element force-displacement equations obtained by the finite-element method (Ref 13) satisfy the constitutive relations and compatibility throughout

the element and approximately satisfy equilibrium and the boundary conditions throughout the element. The discrete-element method satisfies the constitutive relations and equilibrium throughout the element but only approximates compatibility and the boundary conditions throughout the element. For certain special cases either method may give the "exact" force-displacement equations.

CHAPTER 4. CONVERSION OF ENGINEERING INPUT

Much of the data describing a plane frame readily available to an engineer is not in the form needed to solve the computer model of the frame. Thus either the engineer has to perform the tedious and repetitive calculations necessary to convert the data, or this conversion can be incorporated into the computer program. The equations needed for converting the engineering data into a form compatible with the theory presented in Chapters 2 and 3 are given here and are made internally in the computer program discussed in the next chapter.

Joint Coordinates

The coordinates of each joint in the frame are used to calculate the direction cosines of the frame members. The engineer is more likely to have the projections of the members on the coordinate axes than the actual coordinates of each joint. Thus the offsets or projections x_0 and y_0 as shown in Fig 6 are a more logical choice for the input of the frame geometry.

If the coordinates of one reference joint are given, then the coordinates of a second joint can be computed by adding the appropriate offsets to the coordinates of the first joint. A third joint can be referenced by offsets to either of the first two, etc. In general, if joint i has been located and has coordinates x_i and y_i then the coordinates of joint j, x_j and y_j are given by

$$\mathbf{x}_{\mathbf{j}} = \mathbf{x}_{\mathbf{i}} + \mathbf{x}_{\mathbf{0}} \tag{4.1}$$

and

$$\mathbf{y}_{\mathbf{i}} = \mathbf{y}_{\mathbf{i}} + \mathbf{y}_{\mathbf{o}} \tag{4.2}$$

The member's direction cosines α and β are given by

Fig 6. General frame member.

$$\alpha = (x_j - x_i)/L$$
 (4.3)

and

$$\beta = (y_{j} - y_{i})/L$$
 (4.3)

where the length of the member L is given by

L =
$$\sqrt{(x_j - x_i)^2 + (y_j - y_i)^2}$$
 (4.5)

Equations 4.3 and 4.4 assume that the member x'-axis is directed from joint i to joint j. The program directs the member x'-axis in the direction that the member stiffness and load types are input.

Member Stiffness and Load Types

Many frames have several members with the same stiffness properties and/or loadings. The terms "stiffness type" and "load type" are used in the program to avoid duplication of input for such members. Two or more members have the same stiffness type if they have the same stiffness properties (length, distribution of axial and flexural rigidities and distribution of elastic restraints) and have their member axes parallel and similarly directed. Two or more members have the same load type if they have the same loadings, length, and similarly directed parallel member axes.

Member Load Data

Consider a member subjected to a variety of loads as illustrated in Fig 6. In general, Q_a is a concentrated load in the direction of the a-axis. Thus Q_x , is a concentrated load in the direction of the member x'-axis, and Q_z is the concentrated moment about the z-axis. And in general, q_{ab} is a distributed loading in the direction of the a-axis and has its intensity per unit of length along the b-axis. Hence q_{yx} , is a load in the direction of the structure y-axis and has its intensity per unit of length along the member x'-axis. Such a load might be the member's own weight, if the structure y-axis is vertical.

A load is positive if directed in the positive sense of the direction axis or, in the case of a moment, if it is counterclockwise in the x-y plane.

Describing member loads in terms of Q_a and q_{ab} , giving the distance from a reference point to Q_a and the distance from a reference point to the starting and stopping points of q_{ab} is a convenient method of inputting member loads. However, the discrete-element model of Chapter 3 requires loads to be in the direction of the member axes and acting only at stations. Thus general member loads must be transformed into member coordinates and discretized to station values. The transformation of concentrated loads from the structure axes to member axes is accomplished by multiplying by the appropriate direction cosines α and β and summing as follows:

$$Q_{x'} = \alpha Q_{x} + \beta Q_{y}$$
(4.6)

$$Q_{y}' = -\beta Q_{x} + \alpha Q_{y}$$
(4.7)

and

$$Q_{z'} = Q_{z}$$
(4.8)

Distributed loads in the direction of the structure axes but with their intensity per unit of length along the member x'-axis transform in the same manner:

$$q_{x'x'} = \alpha q_{xx} + \beta q_{yx}$$
(4.9)

$$q_{y'x'} = -\beta q_{xx} + \alpha q_{yx}$$
(4.10)

and

$$q_{z'x'} = q_{zx} \tag{4.11}$$

The term $q_{z'x'}$ (not shown in Fig 6) is a moment per unit of length and probably not useful for normal design but is included for generality.

Distributed loads directed in one structure direction per unit of length in the other structure direction are transformed by Eqs 4.9 and 4.10 and then multiplied by the absolute value of the direction cosine between the member axis and the axis to which the intensity is referenced to give

$$q_{x'x'} = \alpha q_{xy} \left| \beta \right| + \beta q_{yx} \left| \alpha \right|$$
(4.12)

and

$$q_{y'x'} = -\beta q_{xy} \left| \beta \right| + \alpha q_{yx} \left| \alpha \right|$$
(4.13)

Distances to concentrated loads, etc., may be input in structure coordinates, x and y, and then divided by the appropriate direction cosine to give the distance along the member axis, x', as follows:

$$\mathbf{x'} = \frac{\mathbf{x}}{\alpha} \tag{4.14}$$

or

$$\mathbf{x'} = \frac{\mathbf{y}}{\mathbf{\beta}} \tag{4.15}$$

Discretizing Member Loads

The idea of replacing a complicated loading system with a simpler statically equivalent system is not new. Newmark's classic paper (Ref 12) gives a good practical discussion of the concept and a theoretical treatment is given in a paper by Mises (Ref 11). Mises points out the lack of generality of St. Venant's principle and gives a better criteria for the replacement of one load system by another.

Using Mises criteria a system of loads may be replaced by an equivalent system if the static difference of the two systems is zero and remains zero when the two systems are rotated through an arbitrary angle. Such systems are said to be astatically equivalent. Then, if the real loading system and the astatically equivalent loading system are contained within a circle of diameter ϵ , the error in replacing the original system with the equivalent system will be of order ϵ^2 .

Consider a concentrated load $Q_{y'}$ as shown in Fig 7(a). The load may be imagined to be applied to a simple stringer supported at stations i and i+1. Such a stringer would give reactions at i and i+1 as follows:

$$\hat{p}_{i}^{2} = Q_{y'}(2h - c)/2h$$
 (4.16)

and

$$\hat{p}_{i+1}^2 = Q_{y'}c/2h$$
 (4.17)

The terms \hat{p}_i^2 and \hat{p}_{i+1}^2 are the concentrated station loads required for the member analysis of Chapter 3 and are astatically equivalent to the actual load Q_y , . Both loading systems are contained within a circle of diameter 2h thus the error is of the order $(2h)^2$.

A load parallel to the member Q_{χ} , could be arbitrarily transferred to either station i or i+l and it would still be statically equivalent to the original load but it would violate the principle of astatic equivalence. However, if formulas similar to Eqs 4.16 and 4.17 are used, the desired results are obtained. That is:

$$\tilde{p}_{i}^{1} = Q_{x'}(2h - c)/2h$$
 (4.18)

$$\tilde{p}_{i+1}^{1} = Q_{x'}c/2h$$
 (4.19)

A couple can be considered to be a system composed of two equal and oppositely directed forces a small distance apart. The forces may be transferred by Eqs 4.16 and 4.17 which has the effect of transferring the couple by Eqs 4.20 and 4.21.

.

.

Fig 7(a). Concentrated loads.

Fig 7(b). Distributed Loads.

.

Fig 7. Member loads in member coordinates.

$$\tilde{p}_{i}^{3} = Q_{z'}(2h - c)/2h$$
 (4.20)

$$\tilde{p}_{i+1}^3 = Q_z r^{c/2h}$$
 (4.21)

Linearly distributed loads such as $q_{y'x'}$ (shown in Fig 7(b)) may be first transformed into equivalent concentrated loads as suggested in the figure. A concentrated load is calculated for each element of the member that has any of the distributed loading acting on it. The formulae for the resultant of a linear load and its location may be found in any standard handbook. The concentrated loads thus found may be distributed by formulas 4.16 and 4.17. Higher ordered load distributions may be represented by the user as a series of linear loadings.

Distributed axial loadings $q_{x'x'}$ and distributed rotation loadings $q_{z'x'}$ may be handled in a similar manner. The similarity of the techniques is such that the computer program developed uses the same subroutines for all three types of loads (lateral, axial, and rotational).

Discretizing Member Stiffness Data

All member stiffness data are assumed to be given with respect to the member axes, as shown in Fig 6. That is, the cross-sectional area A is normal to the member x'-axis, the moment of inertia I is about the member z'-axis, $s_{x'}$ is a distributed elastic spring restraint acting parallel to the member x'-axis, $s_{y'}$, is a distributed elastic restraint acting parallel to the member y'-axis, and $s_{z'}$, is a distributed rotational elastic restraint acting about the member z'-axis. Concentrated values of elastic restraint are not permitted.

It is shown in Appendix 1 that using the average values of EI and AE for a linear variation of these properties over an element gives a solution with second order converging properties. A second order converging solution is one in which the error decreases in proportion to the square of the element size. This is compatible with the astatic equivalencing of loads just described. Higher order variations in EI and AE may be specified by the user as a series of linear variations to achieve any desired degree of accuracy.

A jump in EI or AE in an element, as occurs at a cover plate, could for all practical purposes be handled by using the average values of EI and AE for the element. However, this does not give second order convergence. To achieve this the M/EI and T/AE diagrams for an element may be balanced by choosing appropriate effective values of EI and AE to be used for the element. The term M is the bending moment at any point in the element and T is the axial thrust at any point in the element. Thus the M/EI diagram is the curvature diagram and the T/AE diagram is the axial strain diagram. These effective values should be chosen such that the errors in the positive area of the curvature and strain diagrams are balanced or offset by equal negative areas. This criteria gives

$$\overline{EI} = \frac{2hEI_1EI_2}{c_2EI_1 + c_1EI_2}$$
(4.22)

and

$$\overline{AE} = \frac{2hAE_1AE_2}{c_2AE_1 + c_1AE_2}$$
(4.23)

The terms $\overline{\text{EI}}$ and $\overline{\text{AE}}$ are the effective values to be used for the element of length 2h. The terms $\overline{\text{EI}}_1$ and $\overline{\text{AE}}_1$ are the actual values of $\overline{\text{EI}}$ and $\overline{\text{AE}}$ for a distance c_1 , and $\overline{\text{EI}}_2$ and $\overline{\text{AE}}_2$ are the actual values for a distance c_2 .

Positive values of EI and AE throughout the element are assumed in obtaining Eqs 4.22 and 4.23. A zero value of EI which corresponds to an idealized pinned connection is not allowed interior to a member. However, this is not a practical limitation as a hinge can occur at any structural joint. Hence a structural joint may be defined at the location of the hinge and a member specified on both sides of the hinge.

A more realistic way of handling a reduction in moment resistance, which can only approach an idealized hinge, is to put in a reduced value of EI for a short distance around the hinge.

The discretizing of elastic spring restraints can be done in a fairly complicated manner. However, if the restraints are restricted to distributed values, then a second order converging solution can be obtained by handling the springs exactly as distributed loads. That is by first obtaining equivalent concentrated values and then distributing these to the stations. The same formulae as used for loads can be used here. Concentrated elastic restraints, particularly very large values which might be used to set a displacement, cannot be handled in this manner without introducing unacceptable errors. Hence, the program accepts concentrated spring restraints only at structural joints where they are handled "exactly."

CHAPTER 5. COMPUTER PROGRAM

The computer program FRAME 11 has been written for the linearly elastic analysis of plane frames subjected to static inplane loads and has the restrictions outlined in the Introduction (Chapter 1).

The frame, its supports and loads are specified in input Tables 1 through 7. The results are given in output Tables 8, 9, and 10. These tables will be described after a short discussion of the four problem types the program works. A description of the internal workings of the program concludes this chapter. Chapter 6 gives the example problems of the report and additional details on the program are given in the appendices.

The program solves four distinct types of problems. The distinction of problem types is necessary both to increase computer efficiency and decrease the volume of input the user must supply. All problem types are related to the definition of a structure and its loads. For the purpose of defining the problem types, a structure should be considered to include the members of the frame, the member supports, and the joint supports. Any change in the members, their arrangement, or the supports creates a new structure.

Problem Type 1 - Regular Problem

When a structure is to be analyzed for only one loading it should be input as a problem Type 1 for the most efficient solution.

Problem Type 2 - Parent Problem

When a structure is to be analyzed for more than one loading condition, economics in computer time and man hours may be made by making the first solution a Type 2 problem.

Problem Type 3 - Offspring Problem

A structure previously analyzed as a Type 2 problem may be analyzed more economically for another loading condition by running it as a Type 3 problem.

Up to 20 Type 3 problems may follow a Type 2 problem. Type 3 problems must follow a Type 2 or a Type 3 problem. Only loads can be changed in a Type 3 problem. A computer diagnostic will appear if an attempt is made to change the structure in a Type 3 problem.

Problem Type 4 - Family Problem

When one structure is solved for several load conditions starting with a Type 2 problem the results are stored. This allows the designer to solve a structure for several basic load cases and then combine the results in a linear manner. (Exp. 1.5 dead load + 1.8 live load, etc.) Type 4 problems require only input Tables 1 and 7 and may not follow a Type 1 problem.

Input Tables

A detailed input guide is provided in Appendix 2.

<u>Table 1. Program Control Data</u> - consists of two cards which are required for all problems. The first card specifies the problem type, the tables for which data are held and allows the user to suppress output. The second card specifies the number of data cards in Tables 2 through 7. Data may be held for all types of problems but cannot be held on the first problem of a computer run. Data is generally held from the previous problem but after a Type 4 problem the data from the last problem other than a Type 4 problem may be held.

<u>Table 2. Frame Geometry Data</u> - defines the location of the structural joints of the frame. Joints are required at the intersections of two or more members and at the ends of members. Joints need not be input at concentrated loads but are required at locations of supports (concentrated linearly elastic springs) and at hinges (points of zero flexural stiffness).

The first card of Table 2 gives the total number of frame joints, the reference joint, its coordinates, and the joint location tolerance. The reference joint may be any joint and it may have any coordinates except all joints must have coordinates less than 1.0E + 50. As many additional cards as necessary follow to specify the location of the remaining joints and check the location of as many joints as desired. When joints are located more than once the program compares the old and new coordinates. If the difference in either

coordinate (x or y) is greater than the joint-location tolerance a computer diagnostic appears, otherwise the program averages the old and new coordinates and continues.

The second and succeeding cards give the offsets of new joints with reference to previously defined joints. For example, if joint 3 is the reference joint the second card could locate joint 7 with respect to joint 3. The next card could then locate joint 1 with respect to either joint 3 or joint 7. When several joints are in a straight line and have identical offsets, they may be located with only one card. Joint offsets need not be given where members are, but all joints must be located at least once. The input data is echo-printed in Table 2 and in addition the computed joint coordinates are given.

<u>Table 3. Member-Type Location</u> - locates the members of the frame between the joints defined in Table 2. The use of member stiffness and load types reduces the volume of input required for large frames with repeated members. Two or more members have the same stiffness type if they have the same stiffness properties (length, distribution of axial and flexural rigidities, and distribution of elastic restraints) and have their member axes parallel and similarly directed. Two or more members have the same load type if they have the same loadings, length and similarly directed parallel member axes.

The first card of Table 3 contains the total number of stiffness types and load types in the frame. The second and succeeding cards give the location of the members in the frame and their stiffness and load types.

The members are input going "From" one joint "To" another joint. This orients the member x'-axis in the direction of the "To" joint. The orientation is given with the member output for interpreting results.

When several members with the same stiffness and load type are connected in a straight line, they may be input with only one card.

The stiffness and load types on a data card replace the old values for a member if old values exist. Thus if only one member's stiffness and load type change from the previous problem the data may be held in Table 3 and only the new values of stiffness type and load types given. And obviously, both the stiffness and load types must be given even if only one of them changes.

The input data is echo-printed and in addition the computed member numbers, lengths, and offsets are printed in Table 3.
<u>Table 4.</u> Joint Loads and Restraints - gives joint loads and restraints in the structure x-y-z axes. Frame supports are specified as linearly elastic restraints (springs). Realistic values may be used where available or fictitiously large values may be used to simulate unyielding supports.

A completely fixed support is obtained by specifying large horizontal (x), vertical (y), and rotational (z) springs at a joint. A pinned support would omit the rotational restraint and the free end of a cantilever would have no restraints.

A specified displacement may be enforced by inputting a large spring and a correspondingly large force equal to the spring restraint times the desired displacement.

Each card of Table 4 contains joint loads and restraints for one joint. Only joints with nonzero values need have a data card. No special order of the joints is required in Table 4. The table is accumulative and in addition to the echo-print of the data the accumulated joint data is printed.

Loads are positive if in the direction of the structure axes, thus counterclockwise couples are positive loads. Springs corresponding to stable supports will always be positive.

Table 5. Member Stiffness Data - specifies the stiffness data for the various stiffness types in the frame. One or more data cards are required to define each new stiffness type. Stiffness types must be input in ascending order and when Table 5 is held from a prior problem the first new stiffness type must be one more than the last stiffness type in the prior problem.

Prismatic members without elastic spring restraints require only one data card. Members with variable cross-sections or elastic-spring restraints require two or more data cards and the first card indicates how many additional cards follow.

Connections of members to the joint may be either pinned or rigid and are indicated on the first card for each stiffness type. This option either pins or rigidly attaches the member to the joint but does not in any way serve as a support for the frame (i.e., when a member has a pinned support at its end it must be specified in Table 4 even if a pinned connection to the joint is provided in Table 5).

Distances to locations of changes in stiffness are given from the members "From" joint and may be in either member or structure coordinates

depending upon the axis option chosen. Positive distances are in the direction of the chosen axis.

Either partial or complete member output may be requested in Table 5 for each stiffness type and all members with that stiffness type will have the specified output.

<u>Table 6. Member Load Data</u> - specifies the loadings for the various load types. One or more data cards are required to define each new load type. Load types must be input in ascending order and when Table 6 is held from a prior problem the first new load type must be one more than the last load type in the prior problem.

Members with only uniform loads over their full lengths may be input with only one data card. Other loadings require two or more cards and the first card indicates how many additional cards follow. Four axis options are provided which permit the user to describe the member loads in the most convenient manner. Loads are positive if they are in the direction of the chosen axes, thus, counterclockwise couples are always positive. Distances to concentrated loads and changes in distributed loads are given from the members "From" joint and are positive in the direction of the chosen axes.

Table 7. Compilation Table - specifies the problem numbers of previous problems and their appropriate load factor for a superposition solution. Table 7 has one data card for each previous problem which has a multiplier. No cards are input in Table 7 except for Type 4 problems.

A multiple of a Type 4 problem is not allowed but the data from the previous Type 4 problem may be held and combined with new multipliers. In addition to an echo-print of the data the accumulated multipliers are printed.

Output Tables

<u>Table 8. Joint Displacements and Reactions</u> - gives displacements and reactions for all frame joints. Only supported joints (those with elastic spring restraints) will have nonzero reactions.

Undefined displacements, such as the rotation of a joint to which all members are pinned, or all three displacements of a joint to which no members are connected, are indicated in the output by extremely large displacements. (Refer to example problem 1101.) Joint displacements and reactions are in structure coordinates and positive in the positive coordinate directions. Thus positive rotations are counterclockwise.

<u>Table 9. Member Results</u> - gives, for all members, either member-endforces or detailed output, as requested in Table 5. Member-end-force output consists of the axial forces, shears and bending moments at the ends of the member; complete member output lists the axial, lateral, and rotational displacements as well as the axial force, shear and bending moments at 21 equally spaced points along the member.

For either choice of output, the axial forces, shears, and bending moments are in normal member-sign convention (not a joint-sign convention). Positive axial force produces tension in the member, positive shear tends to raise the end of the member nearest the origin of the member's x'-axis, and positive bending moment produces tension on the bottom side of the member. Positive displacements are in the positive member axes directions, thus, positive rotations are counterclockwise. The direction of the member's x'-axis is as input in Table 3 and is given with the member output for convenience.

Distances to the 21 output points are given along the axis used to specify the members stiffness data and are positive if in the positive axis direction. Regardless of the input options used, the axial force is parallel to and the shear force is normal to the member's x'-axis.

The values of axial force, shear and bending moment are the normal engineering values except that average values are given when there is a double value at an interior point due to a concentrated load or couple.

The maximum equilibrium error in the member is also output with the member's results and should always be a negligible quantity.

<u>Table 10.</u> Joint-Equilibrium Errors - give the errors in equilibrium at the frame joints and should always be negligible except at a joint for which specified displacements are enforced. A valid check of such joints is not possible.

The equilibrium errors at other joints should be scanned by the designer to see that the program is working properly. In considering the relevance of an error the designer might ask what effect the error would have if applied to the joint as a load. Example problem 1201 has one of the largest joint equilibrium errors of the report, an error of 1.2 kip-inches. If this were applied to the joint as a load it would scarcely change the distribution of moments in the members of 8,539 and 8,540 kip-inches respectively.

Program Description

FRAME 11 is written in FORTRAN IV and conforms to the requirements of "American Standard FORTRAN" (Ref 1). The program has been implemented and thoroughly checked on the CDC 6600 computer at the Computation Center of The University of Texas at Austin. Only minor modifications are necessary to convert the program to other machines.

Program flow charts, the glossary of notation, and the FORTRAN listing of programs are in Appendices 3, 4, and 5 respectively. The reader interested in developing a full understanding of the program may wish to refer to these appendices as he reads the remainder of this chapter. In particular, the flow diagram for subroutine FRAM11 should prove helpful.

There are four more or less distinct paths through the program taken by the four problem types. The program will be explained by examining these paths.

Regular Problem

A Type 1 or regular problem is the analysis of a structure for one single loading condition. Type 1 problems, as all problems after the first problem of a run, start by reading in the problem number and problem identification card. The first problem of a run also contains two run identification cards. Then unless the problem number is equal to "CEASE" the program inputs Table 1.

For Type 1 problems, calls are then made successively to JTCORD, MEMLOC, JNTDAT, RDMST, and RDMLD which input Tables 2 through 6, echo-print the data, and after making preliminary computations, print the additional data described earlier in the chapter.

Subroutine RDMST and RDMLD convert the member stiffness and load data from the input coordinates to member coordinates and from that point on all member data is expressed in member coordinates. The transformation to discrete station values is not made at this time, in order to conserve storage.

Subroutine COMP is then called which prints out the table heading for input Table 7 and indicates that there is no data in the table.

In each of the routines which inputs data, checks are made for inconsistencies. If a data error is found the program stops processing that problem, prints out an appropriate error message and searches the remaining data cards for an independent problem. All intermediate cards are listed in the output.

The next step is the calculation of the member's stiffness and fixed-endforce matrices in member coordinates. Members with the same stiffness type will have the same member stiffness matrix; thus, member-stiffness matrices are computed and stored by stiffness type. Members with the same load type need not necessarily have the same stiffness type; hence, the member fixed-endforce matrices are computed and stored for each individual member.

Subroutine FORMST is called to calculate the member's stiffness matrix. FORMST calculates the stiffness matrix using known formulae for prismatic members not elastically restrained. Other members have their stiffness matrix generated by applying the appropriate unit displacements as discussed in Chapter 3.

Members which require the unit-displacement technique first have their stiffness data discretized to station values by subroutine DISCST. Then axial and lateral solutions are performed by subroutine AXIAL and GRIP2A.

Subroutine AXIAL is a short routine for solving the members axial equilibrium equations. The routine, which is a slight modification of previous beam-column solution routines (Ref 9), takes advantage of the fact that the band width of the axial equations are only three terms wide.

Subroutine GRIP2A is the general-simultaneous equations routine of the program and is used to solve the member-equilibrium equations for lateral displacements and rotations and also the joint-equilibrium equations for the joint displacements (vertical, horizontal, and rotational).

GRIP2A calls FSUB1 which calls FSUB12 to generate the member stiffness and load matrix one row at a time. (In the frame solution, GRIP2A calls FSUB1 which in turn calls FSUB11 for the appropriate frame coefficients.)

GRIP2A is a modification of the general recursion-inversion routine GRIP2 reported in Ref 3. The modification reduces the storage required for an incore solution which proves to be the most economical for small and medium sized frames. Only 13 of the 36-member stiffness coefficients need be calculated and stored. SMMT is the storage vector used and the relation of SMMT to the member-stiffness matrix $[K]_k$ is given in Eq 5.1.

$$\begin{bmatrix} K \end{bmatrix}_{k} = \begin{bmatrix} SMMT(1) & & & & & & & & \\ 0 & SMMT(3) & & & & & & \\ 0 & SMMT(4) & SMMT(7) & (SYMMETRIC) & & & & \\ 0 & SMMT(2) & 0 & 0 & SMMT(10) & & & & \\ 0 & SMMT(5) & SMMT(8) & 0 & SMMT(11) & & \\ 0 & SMMT(6) & SMMT(9) & 0 & SMMT(12) & SMMT(13) \end{bmatrix}$$
(5.1)

Subroutine FORMLD is called to calculate the member fixed-end-force matrices. Prismatic members not elastically restrained have their fixed-endforce matrices calculated directly using known formulae. For other members, FORMLD does a member solution for the member subject to its member loads and zero-end displacements.

The member solutions are similar to those discussed in FORMST. Loads are discretized to concentrated station values by subroutine DISCLD.

The frame equilibrium equations are set up and solved by GRIP2A which calls FSUB1 which in turn calls FSUB1 to furnish the appropriate stiffness and load coefficients. FSUB11 is called for each row of equations but forms three rows of equations on every third call from GRIP2A in (3×3) and (3×1) submatrices following the procedure outlined in Chapter 3.

After the frame displacements are found, the corresponding reactions are then computed and the joint displacements and reactions are printed in Table 8.

The sum of the joint loads and reactions are then computed. (When the member-end-forces are subtracted away from these values, the remnants are the equilibrium errors at the joints.)

The member results are then found for each member in the frame by a call to MEMRES. Subroutine MEMRES solves each member for its member loads and the member-end displacements which are compatible with the joint displacements of the frame solution. Loads and stiffnesses are discretized in the same way as previously discussed. Subroutines AXIAL and GRIP2A are then called to solve for the member's axial, lateral, and rotational displacements at each station. The end forces on the ends of the member elements are then computed and an equilibrium check made at each station. The average value of axial force, shear, and bending moment is then computed at alternate stations. (Output is at every other station.)

Subroutine ADJNTER is then called to subtract the member's-end-forces from the partially computed joint equilibrium error. The remnant after all members have had their forces subtracted away should be extremely small and is an indication of how accurately the frame-joint displacements have been computed. It should be noted that some error is introduced due to using the standard stiffness matrices for prismatic members and then evaluating the member-end-forces by the discrete-element solution. This could be avoided by calculating memberend-forces in a different manner (matrix techniques of Chapter 2) for prismatic member. But this would needlessly complicate the program.

As now programmed, the joint equilibrium errors thus serve to indicate the errors both in the solution process and in the two different models (continuous line element versus discrete line element). As shown in the example problems, the errors are negligible.

The member results are printed in Table 9 by subroutine PRINT9. Either complete or partial output is printed, depending on which is requested in Table 3.

The joint equilibrium errors are then printed in Table 10 and the program returns for a new problem.

Parent Problem

A Type 2 or Parent Problem differs from a Type 1 problem only in the tape operations required for a Type 2 problem.

Subroutine COMP forms a list of problem numbers for which the results are saved for future Family Problems. The first problem of the list is the Parent Problem.

After the solution of the frame equilibrium equations by GRIP2A, the recursion multipliers RM and RO are stored on Tape 2 for a Parent Problem so they will be available for future Offspring (Type 2) Problems. Note that since RM and RO are kept in core, they would be available for future solutions except that the routine GRIP2A is used for solving both frame equations and member equations.

56

Then the frame displacements, reactions and joint loads are stored on Tape 1 for future Family (Type 4) problems. The tape is rewound prior to writing data on it since the Parent Problem is the first of a series for which the results are stored.

Similarly, Tape 4 is rewound and the results for six members are written on it at one time. The member results are grouped in order to decrease the number of records written, thus reducing the time for tape operations.

Offspring Problem

A Type 3 or Offspring Problem skips the formation of the member stiffness matrices, since the stiffness data must be identical to the last problem. However, the member-end-forces matrices must be formed as was done for regular and Parent Problems.

Prior to calling GRIP2A for the solution of frame equilibrium equations, RM and RO are retrieved from Tape 2. Then RM and RO need not be calculated again by GRIP2A, thus greatly reducing the solution time for the equations. After the solution, RM and RO are again stored on Tape 2 for additional Offspring Problems.

The frame-joint displacements, reactions, and loads are stored on Tape 1 as was done for the Parent Problem. And member results are stored on Tape 4.

Family Problem

A Type 4 or Family Problem has a completely different path through the program. Input Tables 2 through 6 are not read in. In subroutine COMP, the problem numbers and multipliers are read in and a check is made to see that the problem numbers are in the list of problems (parent and their offspring) for which the results have been saved.

A Family Problem then calls subroutine SUM1 for a superposition solution of frame displacements, reactions, and joint loads, and outputs the displacements and reactions in Table 8.

The preliminary computation of joint equilibrium error is made by adding reactions and loads, as was done for the other problem types, and subroutine SUM2 is called for a superposition solution of the members. SUM2 also calls ADJNTER to complete the joint equilibrium error calculations and PRINT9 to print the member results requested. The joint equilibrium errors are printed in Table 10, and the program returns for a new problem.

.

•

CHAPTER 6. EXAMPLE PROBLEMS

A number of examples have been solved to check the accuracy and usefulness of the program. The results for the truss analyzed in problems 1101-1103 are found to be almost identical to an analysis by statics and virtual work found in Ref 10. Numerous other examples not reported were worked to check the accuracy of the computer solution. Example problems 1201-1207 illustrate the use of the program in a meaningful series of problems for a two-story, twoway bent similar to certain highway structures. The results of this series were compared with independent solutions where feasible, and agreement was obtained in all cases.

The units used for all example problems are kips and inches, though any consistent set of units may be used.

Problems 1101-1103 - Simple Truss

The truss of Fig 8 is analyzed in problems 1101-1103. This simple problem illustrates the savings in input possible when members are repeated in a structure.

In problem 1101, the joints are numbered 1 through 12 across the short direction of the truss. This numbering technique will generally give the most efficient computer solution. However, the program will accept any order of numbering as long as the difference between connected joints does not exceed nine and no joint numbers are omitted. The joints are located in Table 2, taking advantage of the uniform geometry of the problem.

All members are assumed unloaded in accordance with normal truss analysis techniques. Thus, all members are assigned zero load type. However, any member loads which might actually exist could be easily accommodated in a manner similar to the member loads of the bent problem.

All chord members have the same cross-section, modulus of elasticity, length, and orientation and hence are assigned a single-stiffness type, Type 1. Stiffness Type 1 is specified for all bottom chord members with a single card. The top chord is specified in a similar manner. All of the members with

59

Stiff Type	(KSL)	Prismatic I(in ⁴)	Prismatic A(in ²)
1	30,000	40	4.0
2	30,000	2,25	3.0
3	30,000	2.25	3.0
4	30,000	1,0	2.0

.

Joint Number
Stiffness Type

1

All Members Have Load Type O

Fig 8. Truss with unsymmetrical loads.

stiffness Type 1 have their member x'-axis going from left to right because of the manner in which the stiffness types are input in Table 3.

All diagonal members have the same cross-section, modulus of elasticity, and length but they have two different orientations. Hence, two stiffness types are required. All vertical members are identical and thus have the same stiffness type.

Joint loads and restraints are input in Table 4. The restraints used are unrealistically large to mimic the idealized pin and roller supports shown.

The data describing the member stiffness types are input in Table 5 and the pinned-end connections are indicated here. Since the members are prismatic, only one card is required per stiffness type. The minimum output is selected for all members. Axis option 1 is used for all members but does not affect the input for prismatic members.

No cards are input for Tables 6 and 7.

Table 8 gives the joint reactions and displacements. The reactions are identical to the reactions of Ref 12 and the displacement of joint 9 of 1.399 inches compares favorably with the displacement of 1.4 inches found in Ref 10. The joint rotations are undefined since all members were specified as pinnedended and the rotations of 1.0 E+99 indicate this. As anticipated, all shears and bending moments for the members are trivial. The axial forces can be easily verified by statics.

Table 10 gives the joint equilibrium errors and confirms that the solution is valid.

In problem 1102, the effects of rigid connections on the truss' behavior are examined. The stiffness types are modified to indicate rigid connections rather than pinned ones. The results are very similar to 1101 except for small bending moments and shears to which the members are subjected due to the continuity.

In problem 1103, the effects of the roller freezing on the truss of 1102 are investigated. As expected, the displacements and axial forces in the bottom chord are reduced but a large horizontal reaction is developed, which the foundation must resist.

Problems 1102 and 1103 required only a few additional data cards since most of the information could be held from problem 1101. Note, however, that

neither 1102 or 1103 could be worked as an Offspring Problem, since the stiffness of the structure changed in both cases.

Problems 1201-1207 - Two-Story Bent

A two-story bent is analyzed in problem 1201 for the live loads shown in Fig 9. The two columns on the left side of the frame have the same length and cross-sectional properties and are input as the same stiffness type. In order to do this, the pin at joint 1 must be specified as a joint property in Table 4 rather than as a member property in Table 3.

The pinned support is specified in Table 4 by using large vertical and horizontal restraints and no rotational restraint. The fixed support at joint 6 requires all three restraints.

The girders are the only members loaded in problem 1201 and are assigned load Types 1 and 2, as shown in Fig 9(b). All other members are assigned zero load type.

The first five stiffness types are prismatic and require only one card in Table 5 to specify their stiffness data. Stiffness Type 6 requires additional data cards to specify its data. Axis option 2 is used for stiffness Type 6. Therefore, horizontal distances are given to the locations of changes in stiffness. The distances are referenced to the "From" joint as defined by the input of Table 3.

The concentrated live loads are input in Table 6 for load Types 1 and 2. Axis option 3 is used for both members so loads are input in the structure axes and distances are horizontal.

Table 8 gives the joint displacements and reactions. The reactions can be seen to be in equilibrium with the applied loads.

The member results are given in Table 9. Some of the members have only member-end-forces while others have complete output at the twentieth points, as requested in Table 3.

Table 10 gives the joint equilibrium errors, that is, the error in equilibrium of forces and moments at each joint. The maximum error is -1.2 kip-inches, which is negligible when compared with the moment in the members at the joint of 8,340 kip-inch.

In problem 1202, the frame of problem 1201 is modified by adding a column below joint 4, as shown in Fig 10. The resulting structure is analyzed for the live loads of problem 1201.

(a) Geometry and stiffness types.

Fig 9. Two-story bent without interior column.

(a) Geometr	y and	stiffness	types.
-------------	-------	-----------	--------

(b) Wind load.

64

Only one additional joint has to be located in Table 2 and one additional member has to be located in Table 3. The member going from joint 9 to joint 4 is assigned stiffness Type 7 and load Type 0. Stiffness Type 7 is defined in Table 5. The end restraint on the column at joint 9 is input in Table 4.

The results of problem 1202 show that the displacements and bending moments are reduced by the addition of the column. The member results for the added member 10 show the variation in axial force, shear, and bending moment, as well as displacements, and could be extremely useful for design.

Problem 1202 was run as a Parent Problem since it was intended to be the first of a series in which the same structure (no change in stiffness properties) was analyzed for a group of loads. Problem 1203 is then an Offspring solution for the wind loads shown in Fig 10(b).

Four new load types are defined in problem 1203, as shown in Fig 10(b). To save the previous load types for future problems, hold Table 6 and define the new load types as 3-6. Note that in locating a new load type in Table 3, the corresponding stiffness type must also be input. And since problem 1203 is an Offspring Problem, the stiffness types must be identical to problem 1202 or a diagnostic message will occur.

Since all the wind loads shown in Fig 10(b) are normal to the members, axis option 1 is used for all load types. Only one data card is required for each load type since all loads are uniform over the full length of the members.

Problem 1204 is an Offspring solution of the frame defined in problem 1202 for the dead loads indicated in Fig 10. All of the members have a uniform gravity load (dead weight) and, in addition, the girders have concentrated gravity loads located at the same place as the live loads shown in Fig 9(b). Since all members are loaded, for convenience they are assigned a load type equal to their stiffness type. The load types are located in Table 3 and defined in Table 6 with all other data held.

All load types are input using axis option 2 which provides for loads acting in the direction of the structure axis. However, distributed loads have their intensity per unit of length along the member axis. The vertical and horizontal members could be defined using axis option 1 since their member axis coincides with one of the structure axes. If axis option 1 were used for the vertical members, the load would be $q_{x'x'}$ and be input in columns 31-40 instead of 41-50. Problem 1205 is a superposition solution (Family Problem). A factor of 1.25 is applied to the dead load, live load, and wind load acting on the structure defined in 1202. The results could be obtained by hand from the results of 1202-1204, but the cost in man-hours would be far more than the computer costs for the Family Problem. Problem 1206 is a similar solution for 1.5 times the dead load plus 1.8 times the live load.

The column (pile) going from joint 9 to joint 4 is subdivided into two members at the point where the soil restraints start in problem 1207. The frame is then reanalyzed for the dead load and the results compared with problem 1204 (the previous dead-load solution). Subdividing the member into two elements gives a more accurate solution and an idea of the accuracy of the original solution in which the column with soil restraints over part of its length was input as one member.

Joint 10 is input at the ground line and all other joint coordinates are held. Stiffness Type 7 is deleted between joints 9 and 4 by specifying zero stiffness and stiffness Type 8 is input going from joint 10 to joint 4. Stiffness Types 9 and 10 are defined in Table 5.

The results of problems 1204 and 1207 agree within approximately one percent, except for a few locations where very small forces exist such as the tip reaction on the column-pile. Here most of the force has been removed by the axial restraints and the error is about 7 percent or approximately 1 kip. For normal design work, the original solution would certainly be accurate enough.

66

CHAPTER 7. CONCLUSIONS AND RECOMMENDATIONS

A direct matrix solution for plane frames has been developed that allows a designer to quickly solve problems that previously were difficult or impossible to solve.

A revision of the previous discrete element model was made to allow loads and restraints to act both parallel and normal to the members.

A computer program, FRAME 11, has been developed and is documented herein. The program has all the linear analysis capabilities of the program developed in Ref 2 and in addition to having the five features discussed in Chapter 1, on page 2, can work larger problems using the same amount of core storage. The program as presently dimensioned will work a frame with up to 75 joints and 150 members.

In order to satisfy the linear assumptions required for the superposition solutions, the beam-column effect of axial forces on lateral displacements was neglected as in normal practice under existing codes. However, various forms of nonlinear analysis are being more widely recognized by codes and the designer will soon need a more general nonlinear analysis program.

Preliminary studies indicate that the discrete-element model reported herein can be extended to include not only the beam-column effect, but other geometric and large displacement effects as well as nonlinear material properties.

ERROR ANALYSIS OF DISCRETE-ELEMENT MODEL

This page replaces an intentionally blank page in the original. -- CTR Library Digitization Team

APPENDIX 1. ERROR ANALYSIS OF DISCRETE-ELEMENT MODEL

The error in a model (either physical or mathematical) may be estimated in several ways. One widely used method is to compare the results of the model analysis with the results of another model analysis, the other model being generally accepted as an adequate model of the prototype. An accepted mathematical model of a frame member is a continuous line element.

In this appendix, the discrete-element model is shown to give results that agree with the continuous line element to within a predictably small error. The difference in resulting displacements between the two models is shown to be a function of the square of the element's length, i.e., of the order $(2h)^2$. This error is compatible with the method of discretizing loads and elastic restraints discussed in Chapter 4. Thus, as the element size decreases, the difference in the results of the two models rapidly approaches zero.

Consider the discrete element shown in Fig 4 (Chapter 3). Assume that the element is fixed at its left end, i.e., *

$$w_{i-1}^{1} = w_{i-1}^{2} = w_{i-1}^{3} = 0$$
 (A1.1)

Now consider the effect of load f_i^2 only, the moment in the two springs M_1 and M_2 will be found by statics to be

$$M_{1} = \frac{3f_{1}^{2}h}{2}$$
(A1.2)

$$M_2 = \frac{f_1^2 h}{2}$$
 (A1.3)

The results of the derivation concern the change in displacements from one end of an element to the other; hence the actual starting values are immaterial.

These will produce corresponding angle changes Ψ_1 and Ψ_2

$$\Psi_1 = \frac{3f_1^2h^2}{2EI_1}$$
 (A1.4)

$$\Psi_2 = \frac{f_1^2 h^2}{2EI_1}$$
(A1.5)

where EI is the flexural rigidity of the element at midpoint. From the geometry of the model

$$w_i^3 = \psi_1 + \psi_2 = \frac{2f_i^2h^2}{EI_i}$$
 (A1.6)

and

$$w_i^2 = \frac{3h\Psi_1}{2} + \frac{h\Psi_2}{2} = \frac{2.5f_i^2h^3}{EI_i}$$
 (A1.7)

The corresponding displacements will now be derived for a continuous element. The governing flexural differential equation for a continuous line is

$$\frac{d^2 y}{dx^2} = \frac{M}{EI}$$
(A1.8)

where y is the lateral displacement and x is the distance along the element measured from station i-1. Note that actually y'' and x'' are the element coordinates as given in Chapter 3 but are not used here in order to avoid confusion with the prime notation for derivatives.

The terms M and EI are the values of bending moment and flexural rigidity at any point along the element. The moment is easily found by statics to be

$$M = f_{i}^{2}(2h - x)$$
 (A1.9)

For a linear variation in stiffness, EI may be expressed in terms of EI as i

$$EI = EI_{i}(1 - \gamma h + \gamma x)$$
 (A1.10)

where γ is the slope of the EI line divided by EI $_{\mbox{i}}$ Thus, Eq Al.8 gives

$$\frac{d^{2}y}{dx^{2}} = \frac{f_{i}^{2}(2h - x)}{EI_{i}(1 - yh + yx)}$$
(A1.11)

Integrating Eq Al.11 gives

$$\frac{dy}{dx} = \frac{f_i^2}{EI_i} \left(\int \frac{2hdx}{1 - \gamma h + \gamma x} - \int \frac{xdx}{1 - \gamma h + \gamma x} \right)$$
(A1.12)

$$\frac{EI_{i}}{f_{i}^{2}}\left(\frac{dy}{dx}\right) = \frac{-x}{\gamma} + \frac{(1+\gamma h)}{\gamma^{2}} \ln (1-\gamma h+\gamma x) + C_{1}$$
(A1.13)

 C_1 is constant which can be evaluated by using the boundary condition that at the left end the slope (dy/dx) is zero. Solving for C_1 and substituting in Eq Al.13 gives

$$\frac{\text{EI}_{i}}{f_{i}^{2}} = \left(\frac{\text{dy}}{\text{dx}}\right) = \frac{-x}{\gamma} + \frac{(1+\gamma h)}{\gamma^{2}} \ln\left(\frac{1-\gamma h+\gamma x}{1-\gamma h}\right)$$
(A1.14)

Integrating Eq Al.14 and evaluating the constant of integration C_2 yields

$$\frac{EIv}{f_{1}^{2}} = \frac{-x^{2}}{2v} + \frac{(1 + vh)(1 - vh + vx)}{v^{3}} \left[\ln\left(\frac{1 - vh + vx}{1 - vh}\right) \right] + \frac{(1 - vh)(1 + vh)}{v^{3}}$$
(A1.15)

At the right end of the element (x = 2h), Eq A1.14 gives

$$\frac{dy}{dx} = \frac{f_i^2}{EI_i} \left[\frac{-2h}{\gamma} + \frac{(1+\gamma h)}{\gamma h} \ln \left(\frac{1+\gamma h}{1-\gamma h} \right) \right]$$
(A1.16)

Expanding the natural logarithm function in a Taylor series gives

$$\frac{dy}{dx} = \frac{f_i^2}{EI_i} \left(2h^2 + \frac{2\gamma h^3}{3} + higher-order terms \right)$$
(A1.17)

This differs from the slope at the left end of the element in the discrete-element model as given in Eq Al.6 by the error term ϵ^* ,

$$\epsilon \star = \frac{2f_i^2 \gamma h^3}{3EI_i}$$
(A1.18)

and this can be expressed in terms of the elements length 2h as

$$\epsilon \star = \frac{f_i^2 \gamma(2h)^3}{4EI_i}$$
(A1.19)

When m of these elements are connected end to end where

٠

 $m = L/2h \tag{A1.20}$

the total error ϵ will be the sum of the m errors given by Eq A1.19 or Eq A1.21

$$\epsilon = \frac{Lf_{i}^{2}\gamma(2h)^{2}}{4EI_{i}}$$
(A1.21)

Thus, the difference in the slope between the two ends of the element is a function of the square of the element size or of the second order.

Then evaluating the difference between the discrete element's displacement as given by Eq Al.7 and the continuous element's displacement at the right end of the element as given by Eq Al.15, yields an error term of

$$\epsilon = \frac{Lf_i^2(2h)^2}{48EI_i}$$
(A1.22)

Similarly, the lateral displacement and rotation due to a moment, and the axial displacement due to a force parallel to the member, may be shown to give a second-order error term. Thus, as the number of elements increase, the difference between the discrete element and the continuous element rapidly approaches zero. This theory was checked for a large number of examples and confirmed. This page replaces an intentionally blank page in the original. -- CTR Library Digitization Team APPENDIX 2

PROB TYPE 1 - Regular Problem - single solution of structure.

PROB TYPE 2 - Parent Problem - first of a series of solutions of one structure in which the stiffness properties of the structure do not change.

PROB TYPE 3 - Offspring Problem - a solution of a structure previously solved as a Parent Problem (PROB TYPE 2).

PROB TYPE 4 - Family Problem - a combination of multiples of Offspring Problems (PROB TYPE 3) and possibly their Parent Problem (PROB TYPE 2). A multiple of a Family Problem is not permitted but the previous Family Problem may be held. 80

TABLE 3. MEMBER TYPE LOCATION (number of cards per Table 1)

TABLE 4. JOINT LOADS AND RESTRAINTS IN STRUCTURE x, y, z-AXES (number of cards per Table 1)

т

This page replaces an intentionally blank page in the original --- CTR Library Digitization Team

Page 3 of 11

+ If equal to 1, distances are measured along the member x'-axis; if equal to 2, distances are measured along the structure x-axis; if equal to 3, distances are measured along the structure y-axis. Member output distances for shear diagram, etc. are controlled by this option. In all cases the restraints are with reference to the local member (primed) axis. See page 10 of this appendix for an example using the various axis options.

± If blank, detailed output is given; if equal to 1, only member-end-forces are given.

.

‡ If blank, the member is assumed rigidly connected to joint at "From" end. If equal to 1, the member is assumed pinned to joint at "From" end.

If blank, the member is assumed rigidly connected to joint at "To" end. If equal to 1, the member is assumed pinned to joint at "To" end.
TABLE 6. MEMBER LOAD DATA (number of cards per Table 1; number of sets of cards equal to the number of load types defined in this problem)

Member loads may be input by any one of the four axis options outlined below. Q is the concentrated load in the direction of the a-axis. q is the distributed load in the direction of the a-axis and has its intensity per unit of length along the b-axis. Note: Concentrated loads may not be input at a distance of 0.0.

-"From" Joint

Axis Option 4 is identical to Axis Option 3 except distances are in structure y-axis and 4 is input in column 65 of first card.

See page 11 of this appendix for an example using the various axis options.

The member x'-axis goes from the "From" joint to the "To" joint. The "From" and "To" joints are determined by input of Table 3.

TABLE 7. COMPILATION TABLE (number of cards per Table 1; no cards unless PROB TYPE 4)

GENERAL PROGRAM NOTES

The data cards must be stacked in proper order for the program to run.

All numbers must be right justified.

The problem number may contain alphanumeric characters.

TABLE 1. PROGRAM CONTROL DATA

- Type 4 (Family) Problems require only the problem type on the first card and the number of cards in Table 7 on the second card.
- Data are accumulated in Tables 2 through 7 until the corresponding Hold Option is left blank.
- When a nonfamily problem follows a Family Problem the data in Tables 2 through 6 may be held from the last nonfamily problem worked.
- The maximum number of cards accumulated in Table 5 is 75 plus the number of stiffness types.

The maximum number of cards accumulated in Table 6 is 150 plus the number of load types.

Type 1 (Regular) and Type 2 (Parent) Problems may appear at any location in a run. However, Type 3 (Offspring) Problems must follow either their Parent or a related Offspring. Type 4 (Family) Problems must follow either their Parent, a related Offspring, or another Family Problem.

TABLE 2. FRAME GEOMETRY DATA

The first card gives the total number of joints in the frame, which must not exceed 75.

- The reference joint, its coordinates, and the joint location tolerance are given only if the Hold Option for Table 2 is not exercised.
- A joint number may not be deleted in a series until the Hold Option is not used. However, the joint may be structurally deleted by removing all members intersecting at the joint.

Blank fields on data cards, except the first five columns, may be used as desired to aid in coding problems. Information in these fields is ignored by the program.

The maximum difference in joint numbers, for joints that are connected by members is 9.

Joints are numbered from 1 to the total number of joints.

- The reference joint may be any joint and it may have any coordinates, except that it and all other joints must have coordinates less than 1.0E50.
- The second and succeeding cards in Table 2 specify the location of all additional joints in the frame at least once. If the Hold Option is used, only the new joints must be specified.
- All offsets must be "From" a previously located joint "To" another joint. The "To" joint may be a previously defined joint. This allows the user to check the locations of the joints. If the error in the location of the joint is within the joint location tolerance then the solution continues; otherwise, the solution terminates with an appropriate diagnostic.
- The joint location tolerance should allow for normal round-off error. If offsets are input to the nearest 0.01 foot them a joint location tolerance of 0.03 foot usually will be sufficient for a moderate sized frame.
- The repetition of the "To" joint allows the user to locate up to seven joints with one card, if the offsets between each new "To" joint are the same as between the "From" joint and the first "To" joint.
- It is not necessary for offsets to be given at locations where members are. However, the location of all joints must be specified at least once.

TABLE 3. MEMBER TYPE LOCATION

The first card in Table 3 gives the total number of stiffness types and the total number of load types.

- Stiffness and load types (other than zero) are numbered from one to their total number. The total number of stiffness types must not exceed 50. The total number of load types must not exceed 50.
- The total number of members in the frame must not exceed 150.
- Type zero stiffness is used to delete a previously defined stiffness. Type zero load is used to indicate no load on a member. The restrictions on length, orientation, etc., outlined below do not apply to members with type zero stiffness and type zero load.
- In order for two members to have the same stiffness type they must have the same length, the same angular orientation in the frame, and the same stiffness properties with respect to their "From" and "To" joints, i.e., they must have the same member stiffness matrix both in their member coordinate system and the global coordinate system.

Page 7 of 11

In order for two members to have the same load type they must have the same length, the same angular orientation in the frame and the same loading with respect to their "From" and "To" joints.

.

- The member coordinate axes are defined by the "From" and "To" joints specified. The member x'-axis starts at the "From" joint and goes to the "To" joint. The member y'-axis and z'-axis are located from the member x'-axis by the right hand rule.
- All members in the frame must be assigned a stiffness type and a load type. This assignment is not accumulative for a member in the frame, i.e., the last values of stiffness type and load type specified replace the previous values.
- Stiffness and load types for a member must be specified on the same card.
- Up to ten members with the same stiffness and load type may be located with a single card if the "From" joint of each new member is the "To" joint of the previous one.

TABLE 4. JOINT LOADS AND RESTRAINTS

All joint loads and restraints are specified with respect to the structure axes.

Joint loads and restraints are accumulated in Table 4.

Structure supports are input as joint restraints (linearly elastic springs). Complete fixity of a joint may be achieved by putting in very large spring values. No round-off errors are encountered when extremely large values are used unless large values are input and then subtracted away.

Complete freedom of joint movements is obtained by not specifying any restraints at a joint.

A specified displacement may be obtained by specifying a very large restraint and a corresponding force equal to the specified displacement times the large restraint.

TABLE 5. MEMBER STIFFNESS DATA

- Stiffness types must be input in ascending order. If Table 5 is held from the previous problem then the first new stiffness type in Table 5 (if any) must equal the number of stiffness types in the last problem plus one.
- Prismatic members may be input with one card. Members with varying stiffness and/or elastic restraints along their length require two or more cards.
- If more than one card is used to describe a member stiffness type, the prismatic stiffness properties must be left blank.
- Variable stiffness properties must be input continuously in sections starting at the "From" joint and continuing uninterrupted to the "To" joint. This format is illustrated in page 10 of this appendix.

Distances are given from the "From" joint.

- Each section must describe all of the stiffness properties of the member for a length greater than 1/40 of the member's length.
- Constant values of stiffness require one card per section.
- A linear variation in stiffness requires two cards per section.
- Concentrated values of stiffness are not allowed. A point of zero flexural stiffness is input as a pin at a joint. A concentrated spring restraint must be input as a joint restraint.

TABLE 6. MEMBER LOAD DATA

- Load types must be input in ascending order. If Table 6 is held from the previous problem then the first new load type in Table 6 (if any) must equal the number of load types in the last problem plus one.
- Load types with only uniform loads over their full length may be input with only one card. Other loadings require two or more cards.
- If more than one card is used to describe a member load type, the uniform loads on the first card must be left blank.
- Variable, concentrated, and partial uniform loadings must be input in sections but need not be input consecutively and sections may overlap. This format is illustrated on page 11 of this appendix.
- Section lengths must exceed 1/40 of the member's length except for concentrated loads where the "From" and "To" distances are equal. Concentrated loads may not be specified at a distance of 0.0.
- All sections except concentrated loads must have their "To" distance larger in absolute value than their "From" distance.
- Concentrated loads and sections with constant loading require one card. A linear variation in loading requires two cards per section.

TABLE 7. COMPILATION TABLE

- Each Parent Problem starts a series where the Parent solution and succeeding Offspring solutions are stored. Each of these solutions may be multiplied by a multiplier (load factor) and accumulated. The maximum number of consecutive Offspring problems is 20.
- If the Hold Option is used the solution of the preceding Family Problem is added to the solutions of the additional load cases specified in the new Family Problem.

76

Page 9 of 11

Notes: Sections must be input in order.

Linear format is required even if only one of the stiffness properties varies linearly.

A new section must be started when a change in the variation of any of the stiffness properties occurs.

There is no restriction on the length of a section except it must exceed 1/40 of members length.

"From" and "To" joints are set by input in Table 3.

o - One Cord for Concentrated Loads

. .

• - One Card for Sections with Uniform Loads

*- Two Cards for Sections with Linearly Varying Loads

Notes:

Sections Need Not be Input in Order.

Concentrated Loads May Not be Input at a Distance of 0.0.

There is No Restriction on the Length of a Section Except that it Must Exceed 140 of the Member's Length. "From" and "To" Joints Set by Input in Table 3.
